

Lecture 12:

A Basic Snooping-Based Multi-Processor Implementation

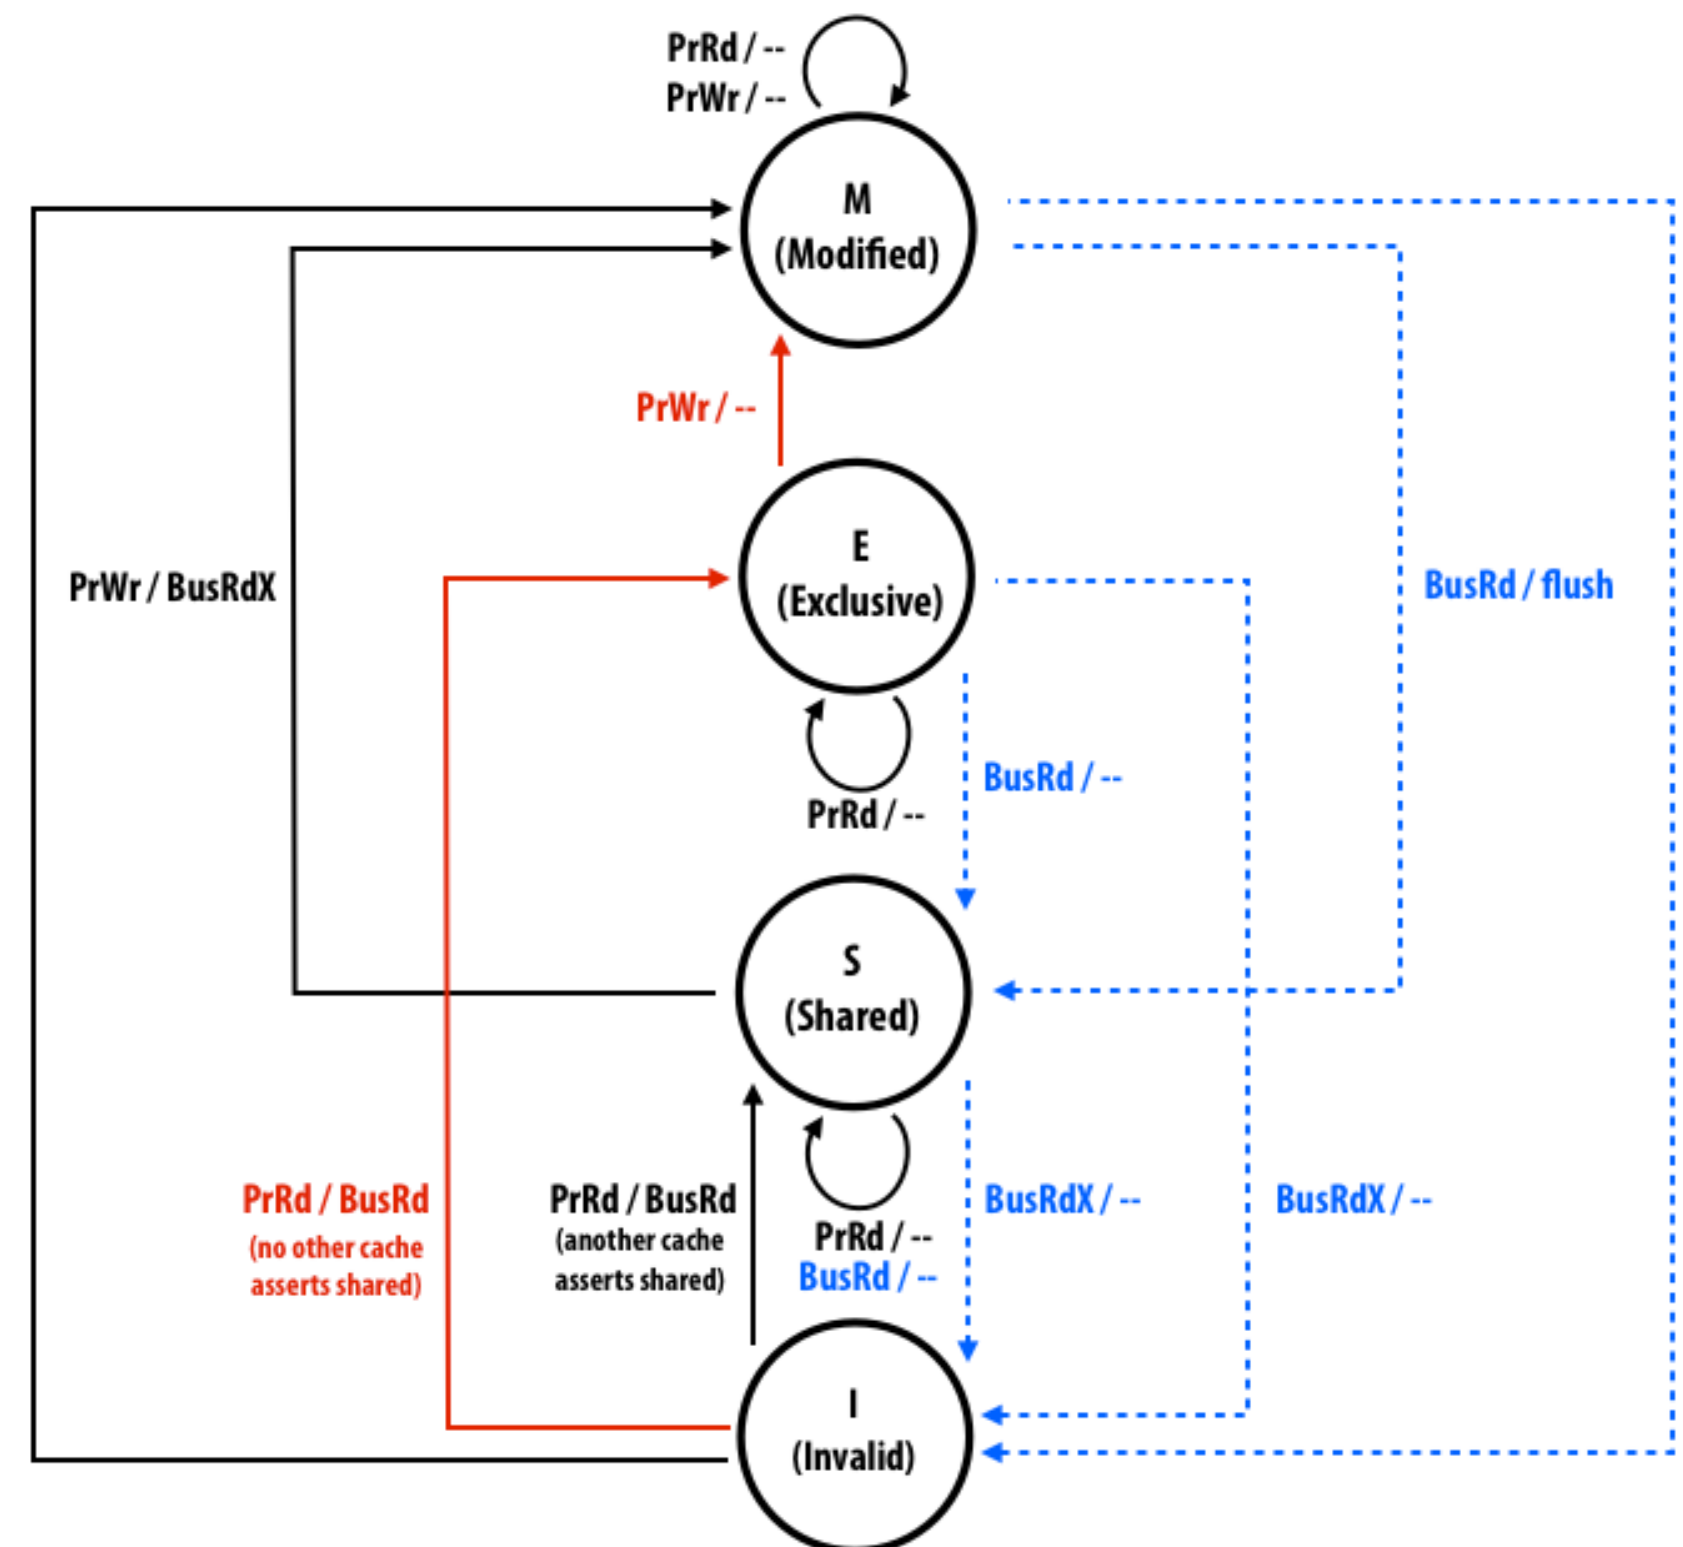

**Parallel Computer Architecture and Programming
CMU 15-418/15-618, Spring 2020**

Today: implementing cache coherence

- Wait... haven't we talked about this before?
- Earlier, we talked about cache coherence protocols
 - But our discussion was very abstract
 - We described what messages/transactions needed to be sent
 - We assumed messages/transactions were atomic

Today we will talk about **efficiently implementing** an invalidation-based protocol

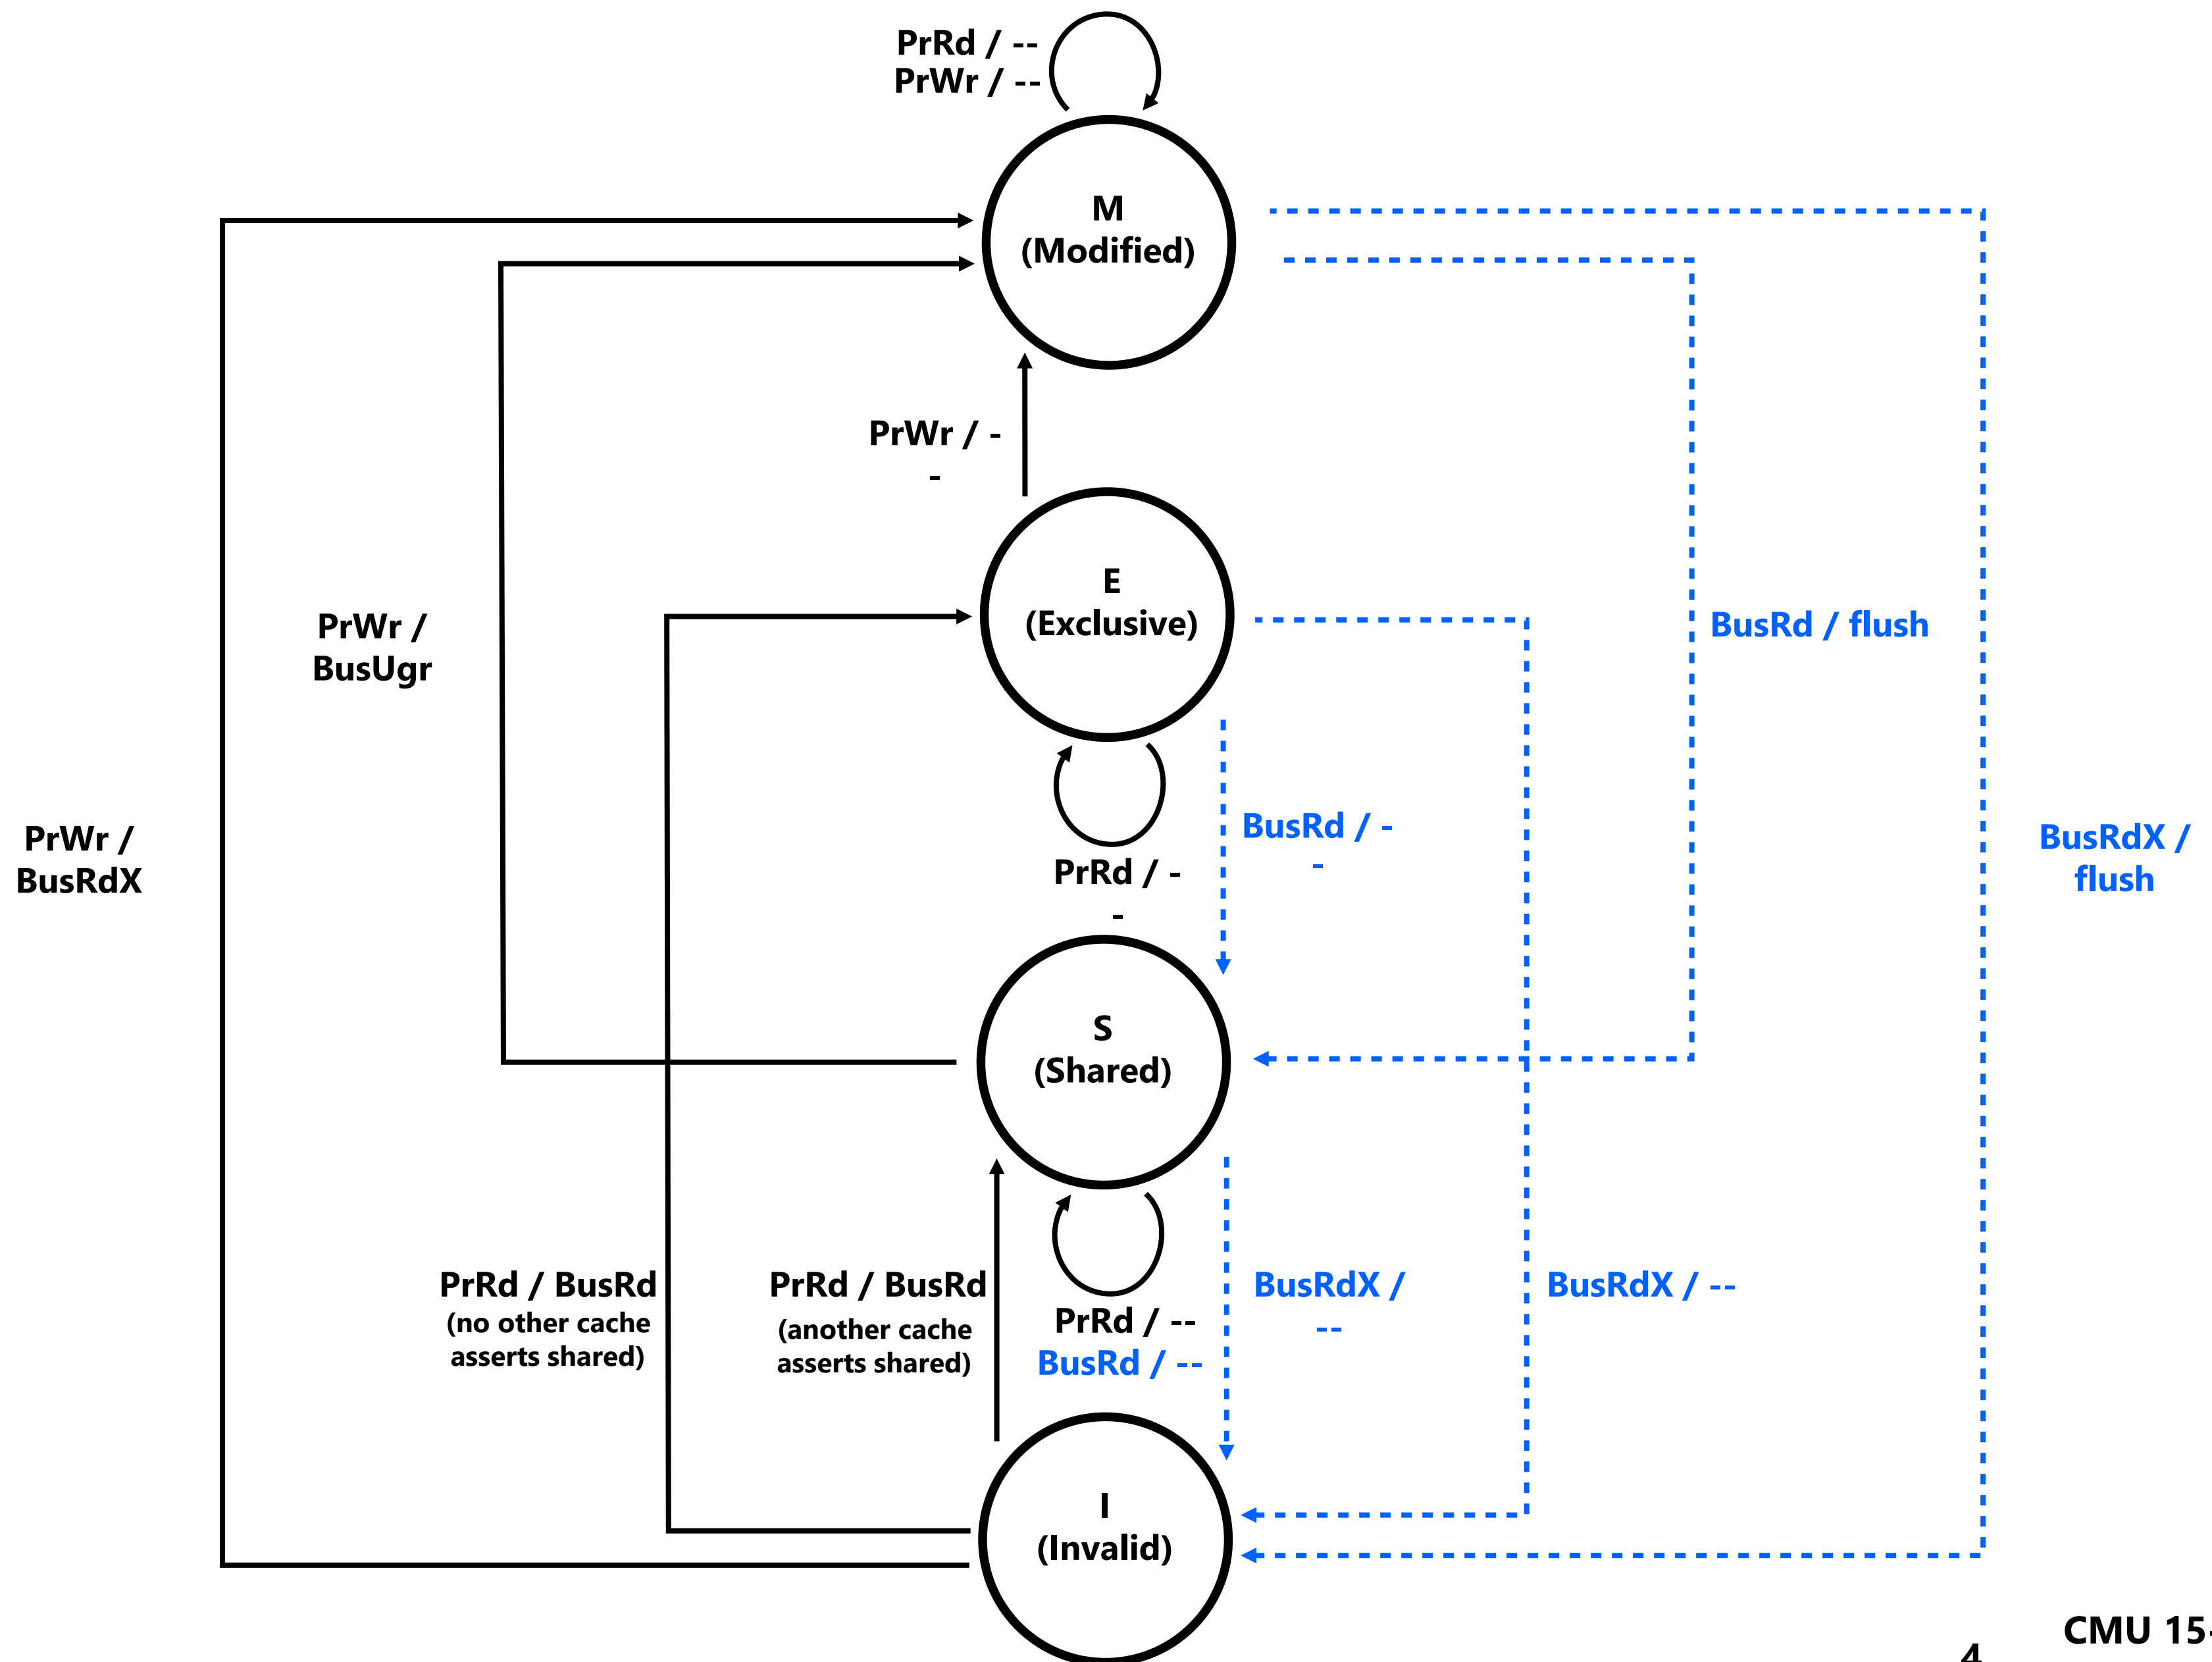

Today's point: in a real machine... efficiently ensuring coherence is complex

The concepts in today's lecture span much more than just hardware implementation

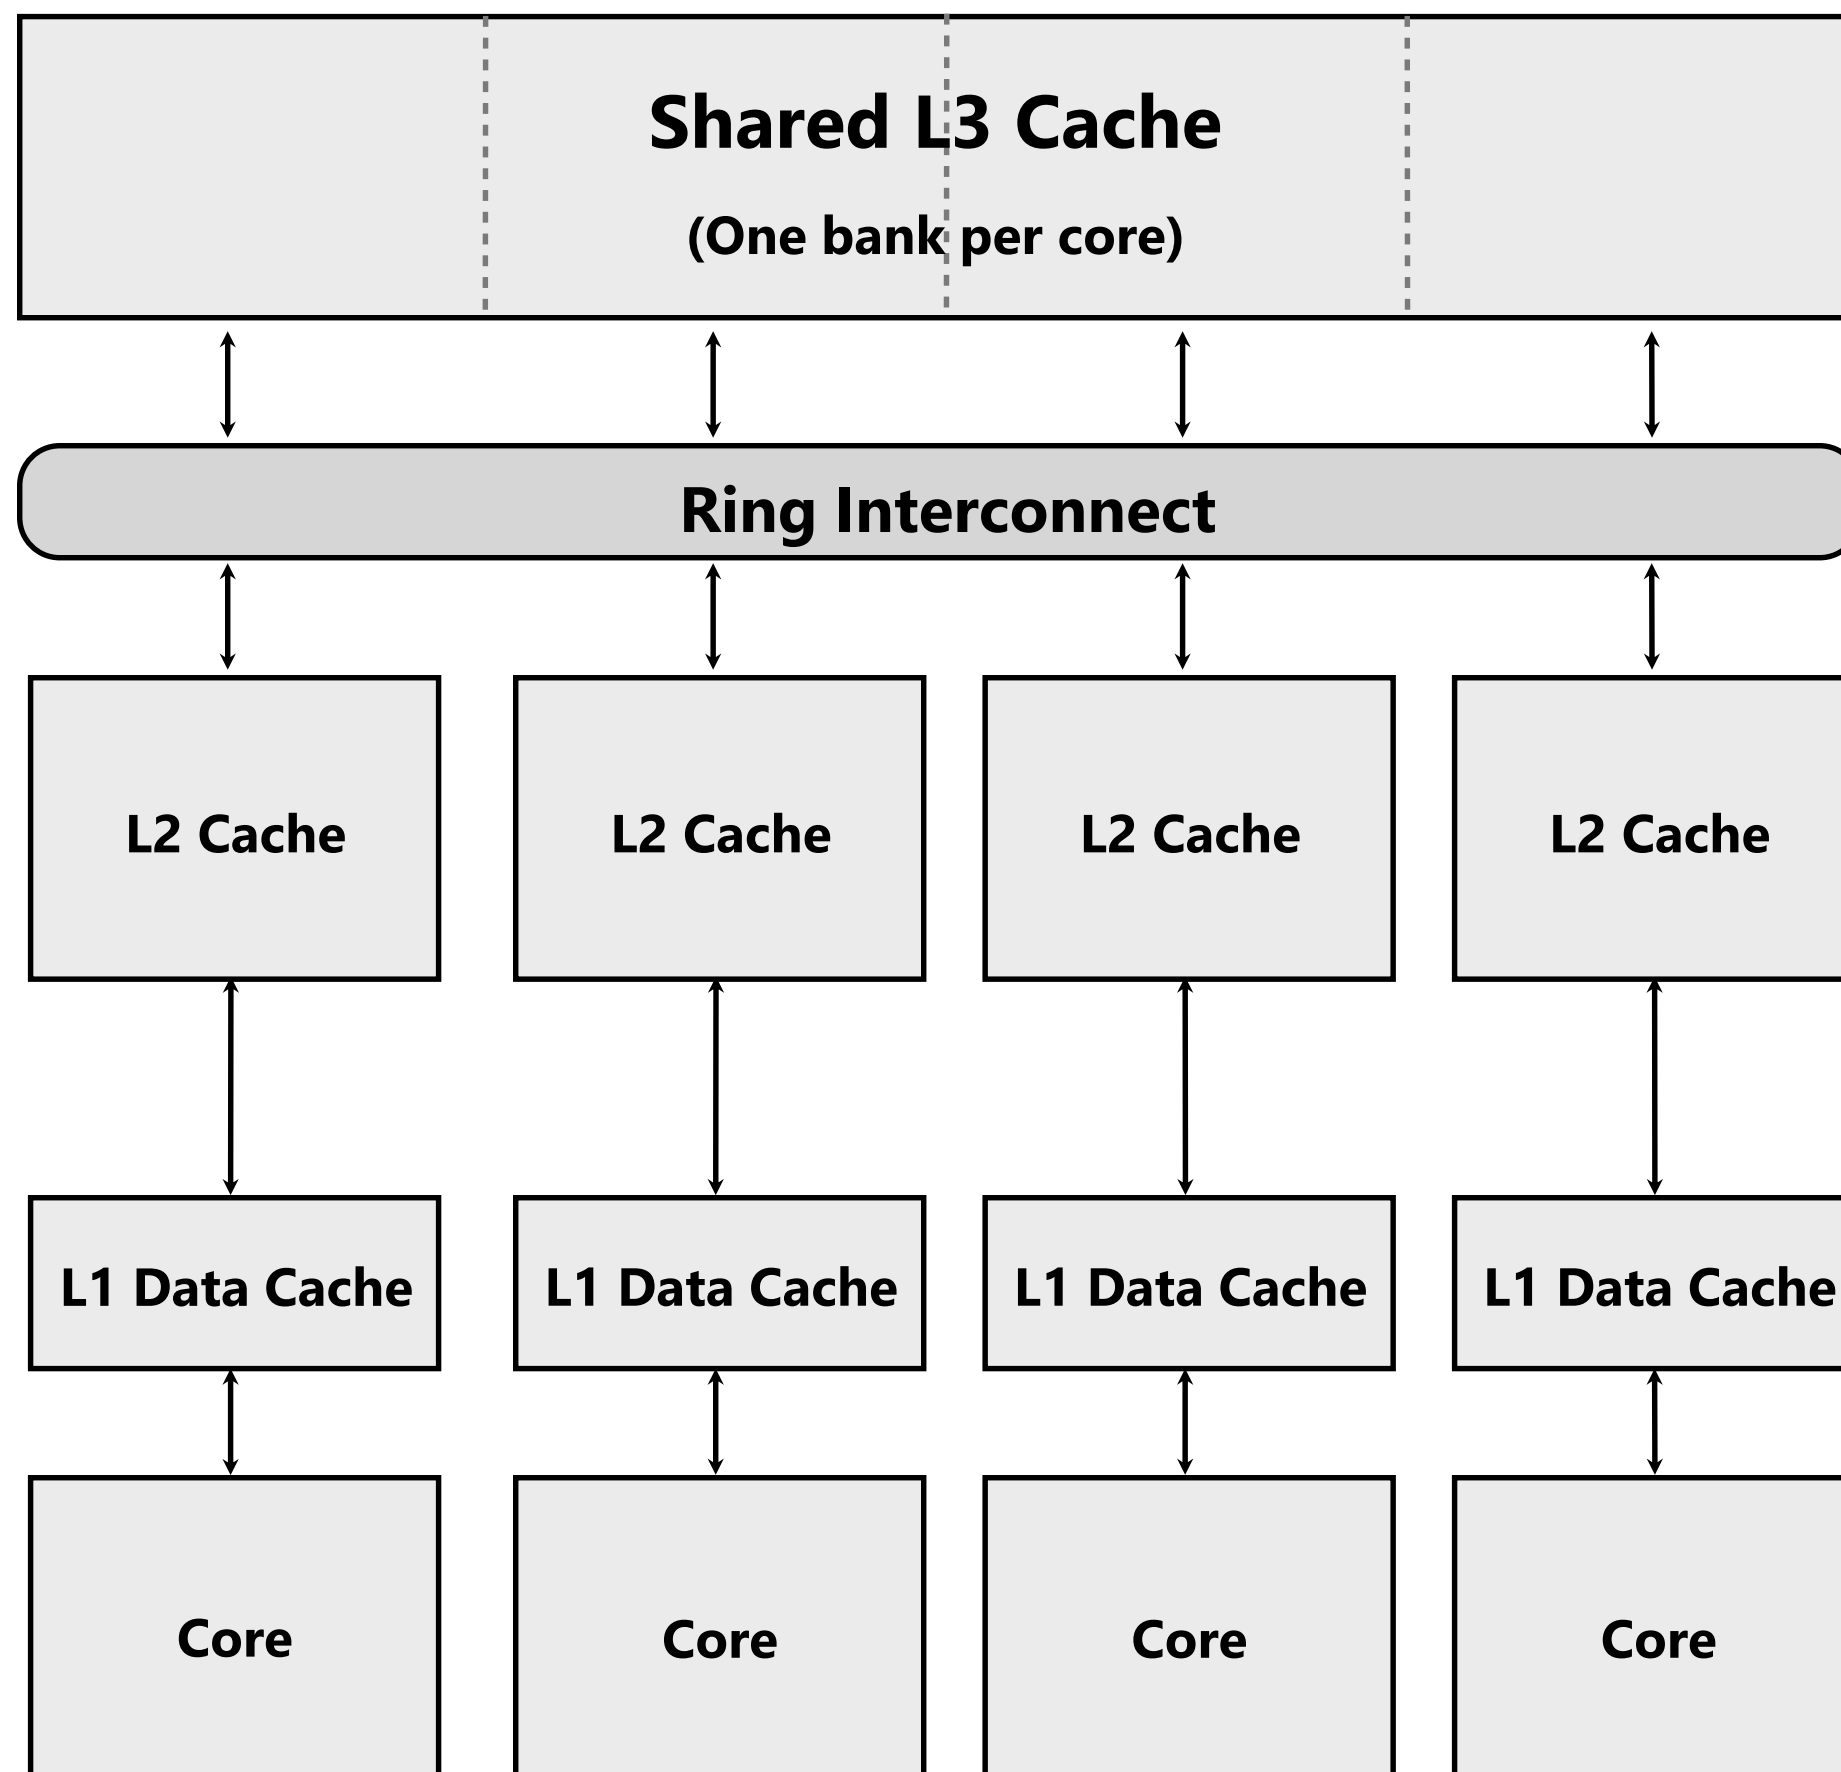

- **The challenges and techniques we describe today (trade-offs between simplicity and performance, challenges of correctness in a parallel system) apply equally well to writing parallel programs**

Review: MESI state transition diagram

Review: multi-level cache hierarchies

Recall Intel Core i7 hierarchy

- **Challenge: changes made to data at first level cache may not be visible to second level cache controller than snoops the interconnect.**
- **How might snooping work for a cache hierarchy?**
 1. **All caches snoop interconnect independently? (inefficient)**
 2. **Maintain "inclusion"**

Inclusion property of caches

- **All lines in closer [to processor] cache are also in farther [from processor] cache**
 - e.g., contents of L1 are a subset of contents of L2
 - Thus, all transactions relevant to L1 are also relevant to L2, so it is sufficient for only the L2 to snoop the interconnect
- **If line is in owned state (M in MSI/MESI) in L1, it must also be in owned state in L2**
 - Allows L2 to determine if a bus transaction is requesting a modified cache line in L1 without requiring information from L1

The goals of our coherence implementation

1. Be **correct**

- Implements cache coherence

2. Achieve **high performance**

3. Minimize “**cost**” (e.g., minimize amount of extra hardware needed to implement coherence)

As you will see...

Techniques that pursue high performance tend to make ensuring correctness tricky.

What you should know

- Concepts of **deadlock, livelock, and starvation**
- Have a basic understanding of **how a bus works**
 - But keep in mind most modern interconnects are NOT buses! (Entire lecture on interconnects soon)
 - Understand **why maintaining coherence is challenging**, even when on simple machine designs
 - How do performance optimizations make correctness challenging?
 - (e.g., how can deadlock, livelock, and starvation occur in coherence implementations, and how are these problems avoided?)
 - Your **mental model** of hardware should be: there are **many components operating in parallel** (even if abstractions don't indicate this is the case)

Terminology

Deadlock
Livelock
Starvation

**(Deadlock and livelock concern program correctness.
Starvation is really an issue of fairness.)**

Deadlock

Deadlock is a state where a system has outstanding operations to complete, but **no operation can make progress.**

Can arise when each operation has acquired a shared resource that another operation needs.

In a deadlock situations, there is no way for any thread (or, in this illustration, a car) to make progress unless some thread relinquishes a resource ("backs up")

More illustrations of deadlock

Credit: David Maitland, National Geographic

Why are these examples of deadlock?

Deadlock in computer systems

Example 1:

A produces work for B's work queue

B produces work for A's work queue

Queues are finite and workers wait if no output space is available

Example 2:

```
const int numEl = 1024;  
float msgBuf1[numEl];  
float msgBuf2[numEl];
```

```
int threadId getThreadId();
```

```
... do work ...
```

```
MsgSend(msgBuf1, numEl * sizeof(int), threadId+1, ...  
MsgRecv(msgBuf2, numEl * sizeof(int), threadId-1, ...
```

Every process sends a message (blocking send) to the processor with the next higher id

Then receives message from processor with next lower id.

Required conditions for deadlock

1. **Mutual exclusion**: one processor can hold a given resource at once
2. **Hold and wait**: processor must hold the resource while waiting for other resources needed to complete an operation
3. **No preemption**: processors don't give up resources until operation they wish to perform is complete
4. **Circular wait**: waiting processors have mutual dependencies (a cycle exists in the resource dependency graph)

Livelock

Livelock

Livelock

Livelock

Livelock is a state where a **system is executing many operations**, but **no thread is making meaningful progress**.

Can you think of a good daily life example of livelock?

Computer system examples:

Operations continually abort and retry

Starvation

State where a system is making overall progress, but **some processes make no progress.**

(green cars make progress, but yellow cars are stopped)

Starvation is usually not a permanent state
(as soon as green cars pass, yellow cars can go)

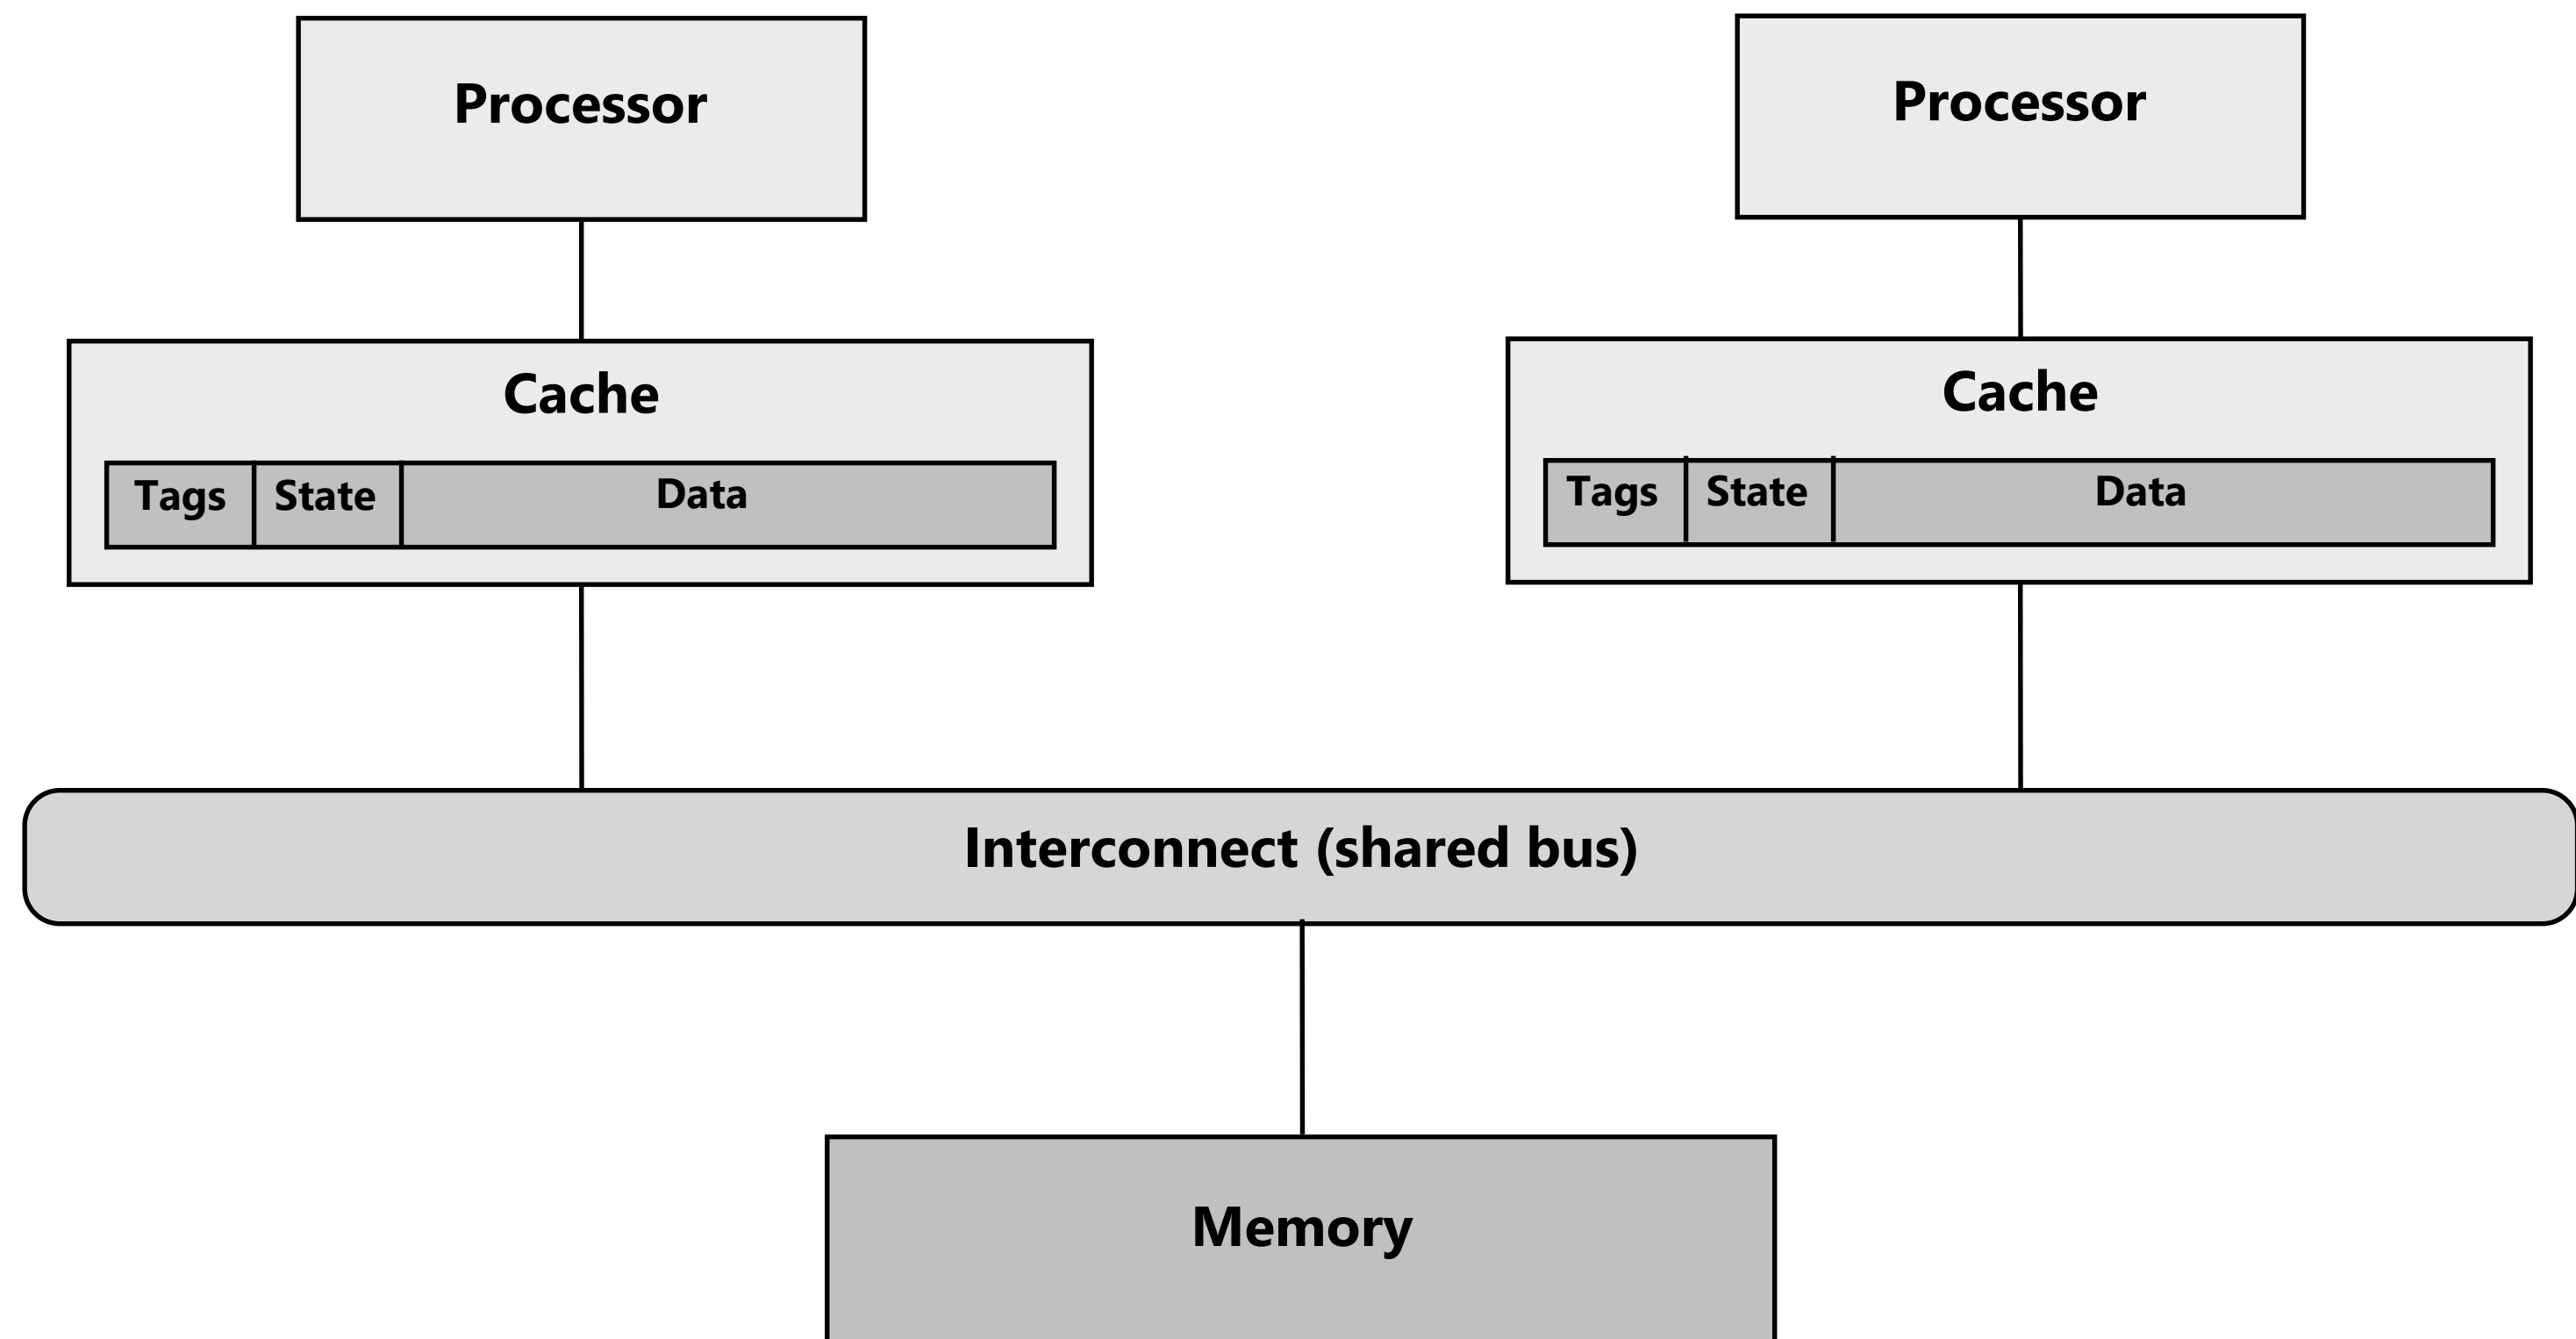

In this example: assume traffic moving left/right (yellow cars) must yield to traffic moving up/down (green cars)

Part 1:

A basic implementation of snooping (assuming an atomic bus)

Consider a basic system design

- One outstanding memory request per processor
- Single level, write-back cache per processor
- Cache can stall processor as it is carrying out coherence operations
- System interconnect is an atomic shared bus (one cache communicates at a time)

Transaction on an atomic bus

1. Client is **granted bus access** (result of **arbitration**)

2. Client places **command on bus** (may also place data on bus)

3. **Response** to command by another bus client placed on bus

4. Next client obtains bus access (**arbitration**)

Cache miss logic on a uniprocessor

1. Determine cache **set** (using appropriate bits of address)
[Assume no matching tags, must read data from memory]
2. Check cache **tags** (to determine if line is in cache)
3. Assert **request for access** to bus
4. **Wait** for **bus grant** (as determined by bus arbitrator)
5. Send **address + command on bus**
6. Wait for command to be accepted
7. **Receive data** on bus

What does atomic bus mean in a multi-processor scenario?

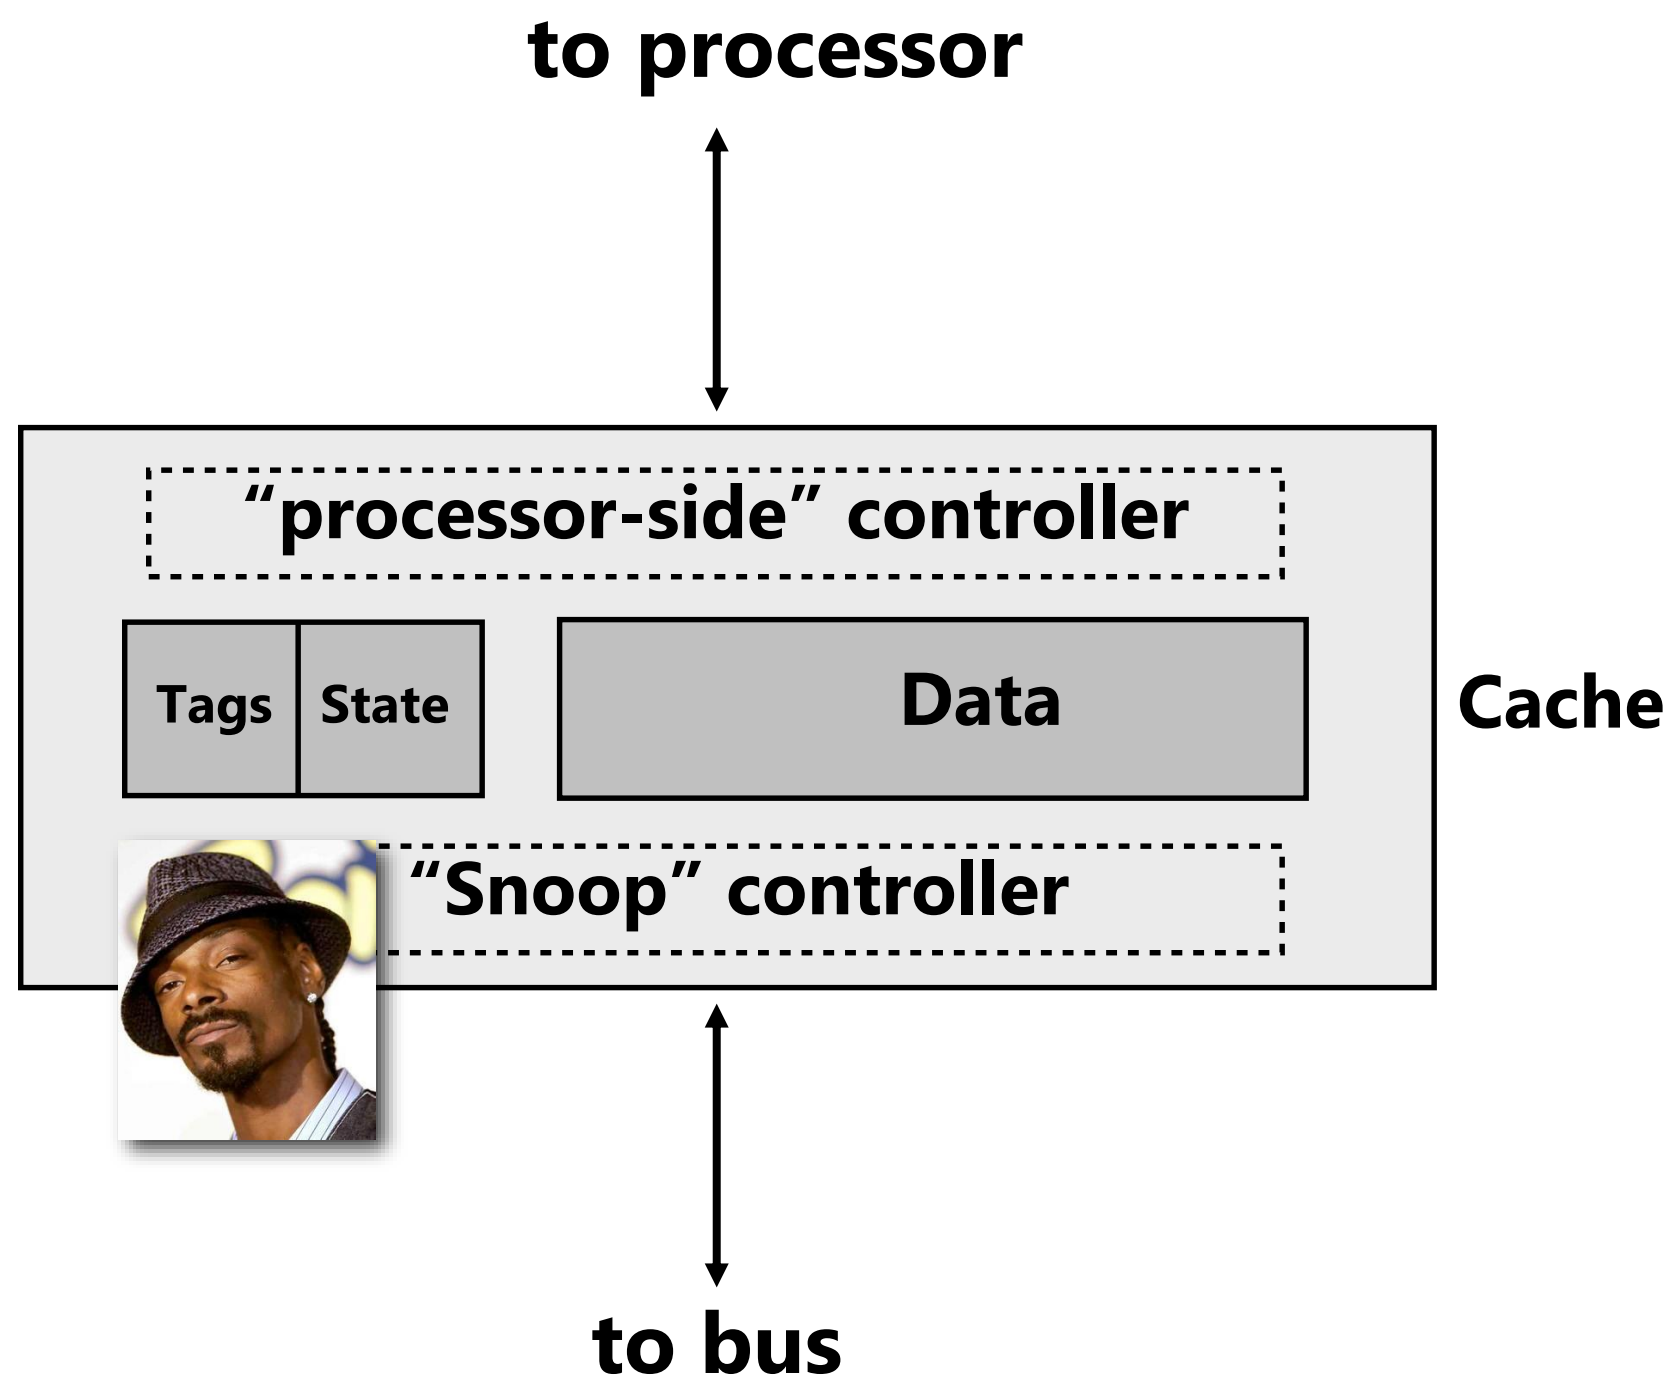

BusRd, BusRdX: no other bus transactions allowed between issuing address and receiving data

Flush: address and data sent simultaneously, received by memory before any other transaction allowed

Multi-processor cache controller behavior

Challenge: both requests from processor and bus require **tag lookup**

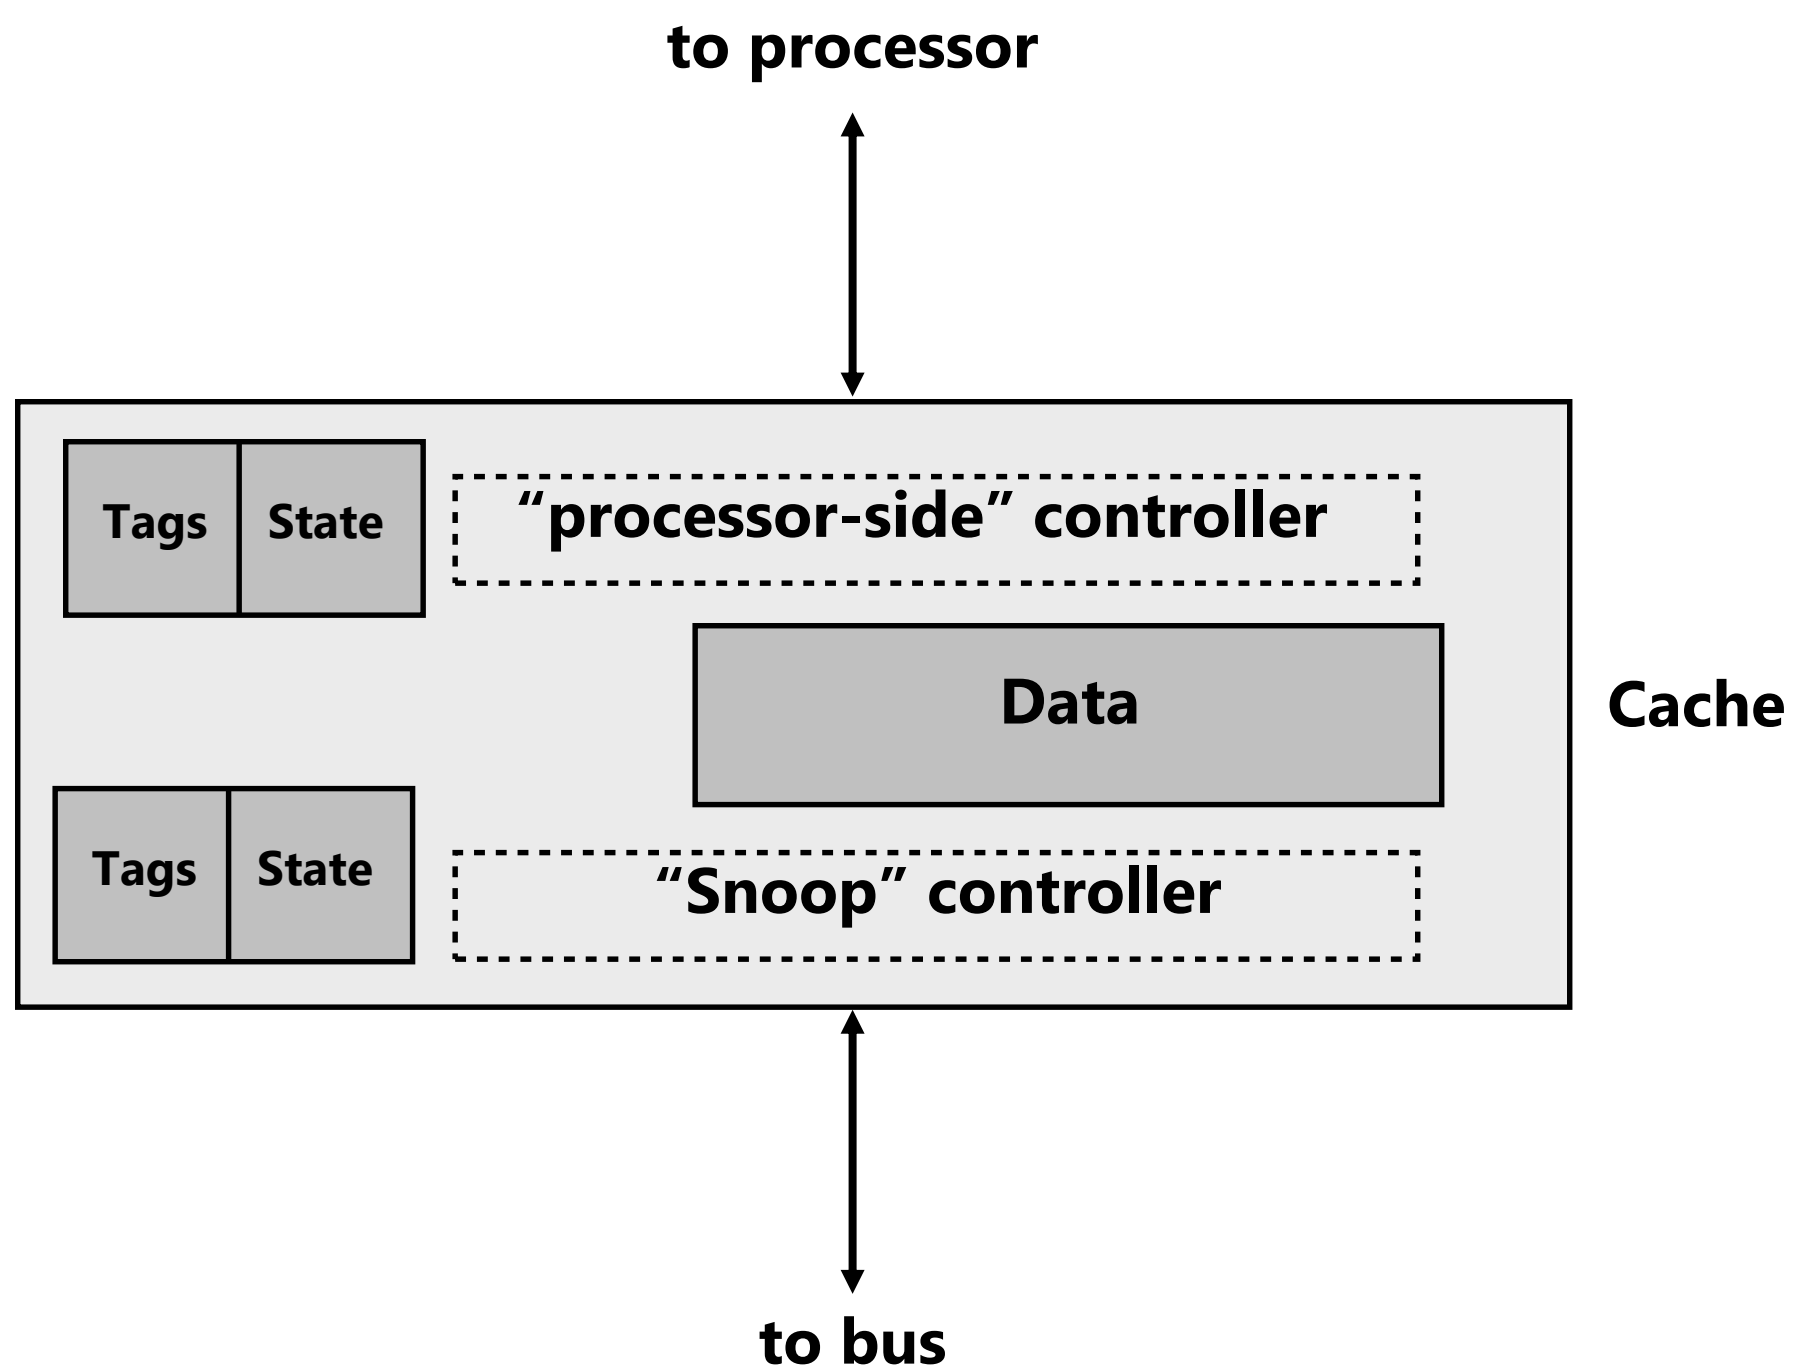

This is another example of **contention!**

If **bus receives priority**:
During bus transaction,
processor is locked out from
its own cache.

If **processor receives priority**:
During processor cache
accesses, cache cannot
respond with its snoop result
(so it delays other processors
even if no sharing of any form
is present)

Alleviate contention: allow simultaneous access by processor-side and snoop controllers

Option 1: cache **duplicate tags**

Option 2: **multi-ported tag memory**

Note: tags must stay in sync for correctness, so tag update by one controller will still need to block the other controller (but modifying tags is infrequent compared to checking them)

Keep in mind: in either case cost of the additional performance is additional hardware resources.

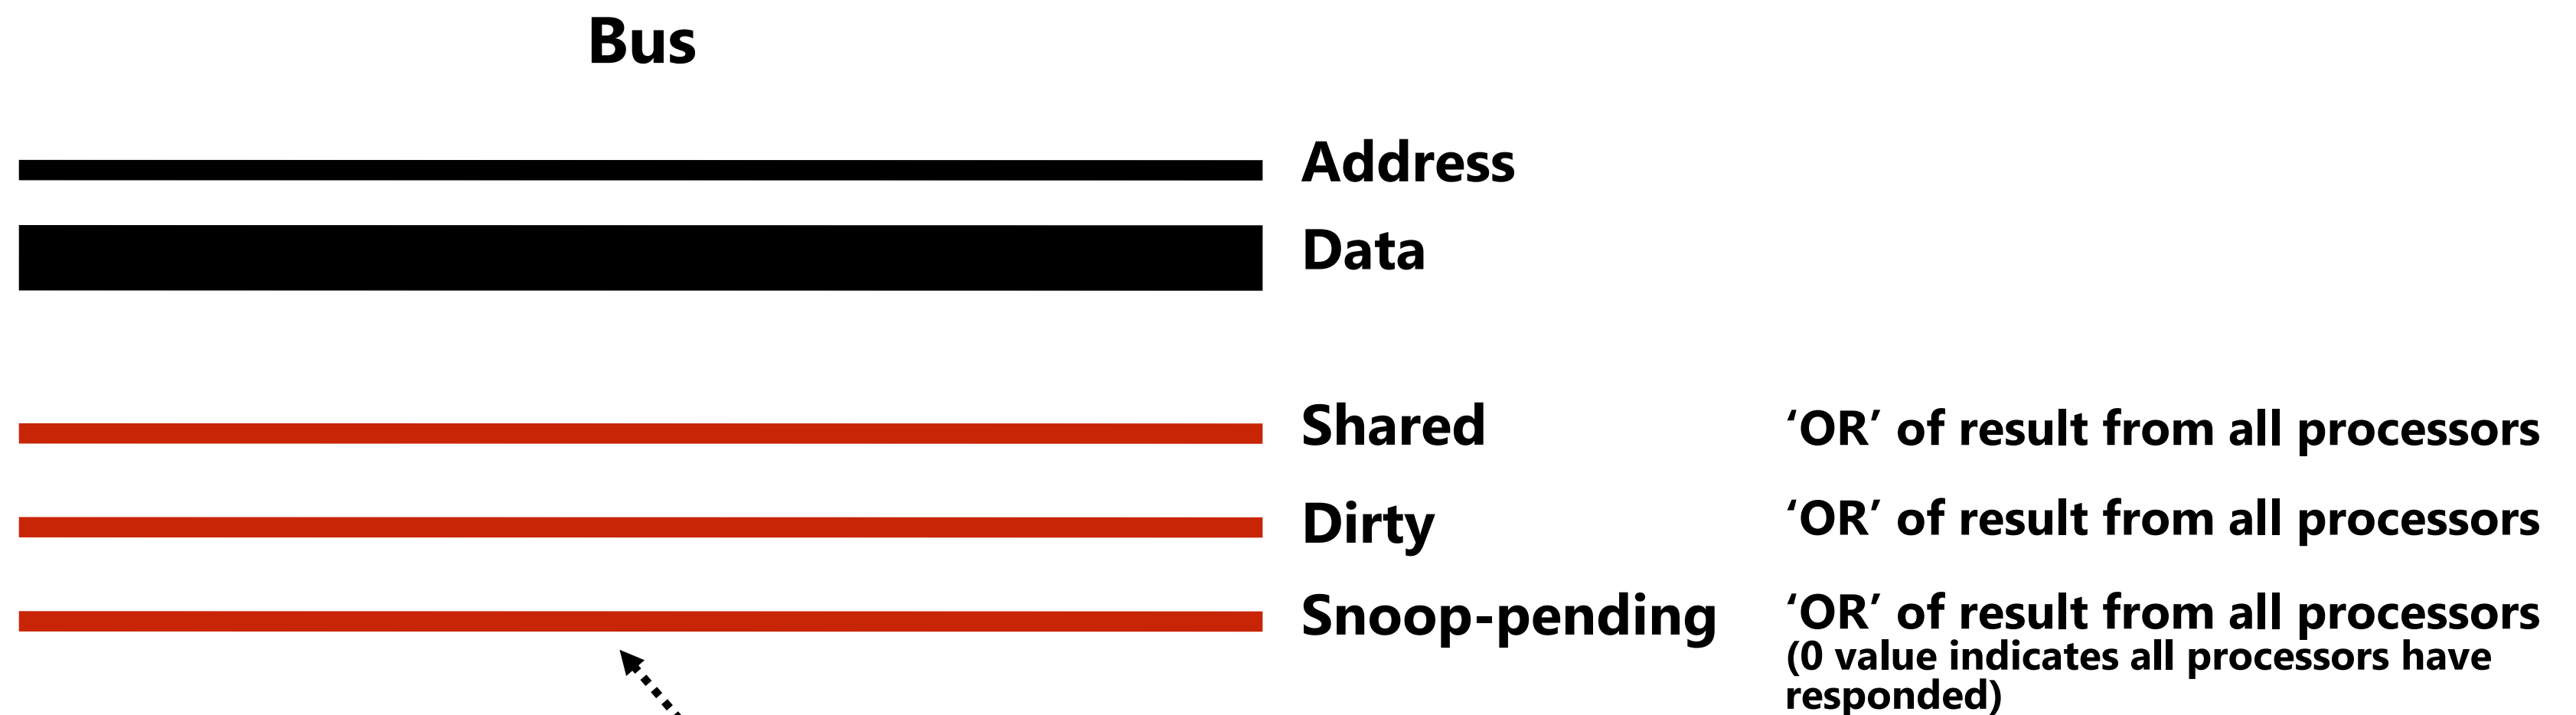

Reporting snoop results protocol in MESI

- Assume a cache read miss (BusRd)
 - Collective response of caches must appear on bus
 - Is line **dirty**? If so, memory should not respond
 - Is line **shared**? If so, cache should load into S state, not E
- Memory needs to know what to do
- Loading cache needs to know what to do

How are snoop results communicated?

When are snoop results communicated?

Reporting snoop results: **how**

**These three lines are additional bus interconnect hardware!
(but $3 \ll \# \text{ address + data lines}$)**

Reporting snoop results: **when**

- Memory controller could **immediately start accessing DRAM**, but not respond (squelch response) if a snoop result from another cache indicates it has copy of most recent data
 - Cache should provide data, not memory
- Memory could **assume one of the caches will service request** until snoop results are valid (if snoop indicates no cache has data, then memory must respond)

Handling write backs

- Write backs involve **two bus transactions**
 1. **Incoming** line (line requested by processor)
 2. **Outgoing** line (evicted dirty line in cache that must be flushed)
- Ideally would like the processor to continue as soon as possible (it shouldn't have to wait for the flush to complete)
- Solution: **write-back buffer**
 - Stick line to be flushed in a write-back buffer
 - Immediately load requested line (allows processor to continue)
 - Flush contents of write-back buffer at a later time

Cache with write-back buffer

these hardware components handle snooping related tasks

these hardware components handle processor-related requests

What if a request for the address of the data in the write-back buffer appears on the bus?

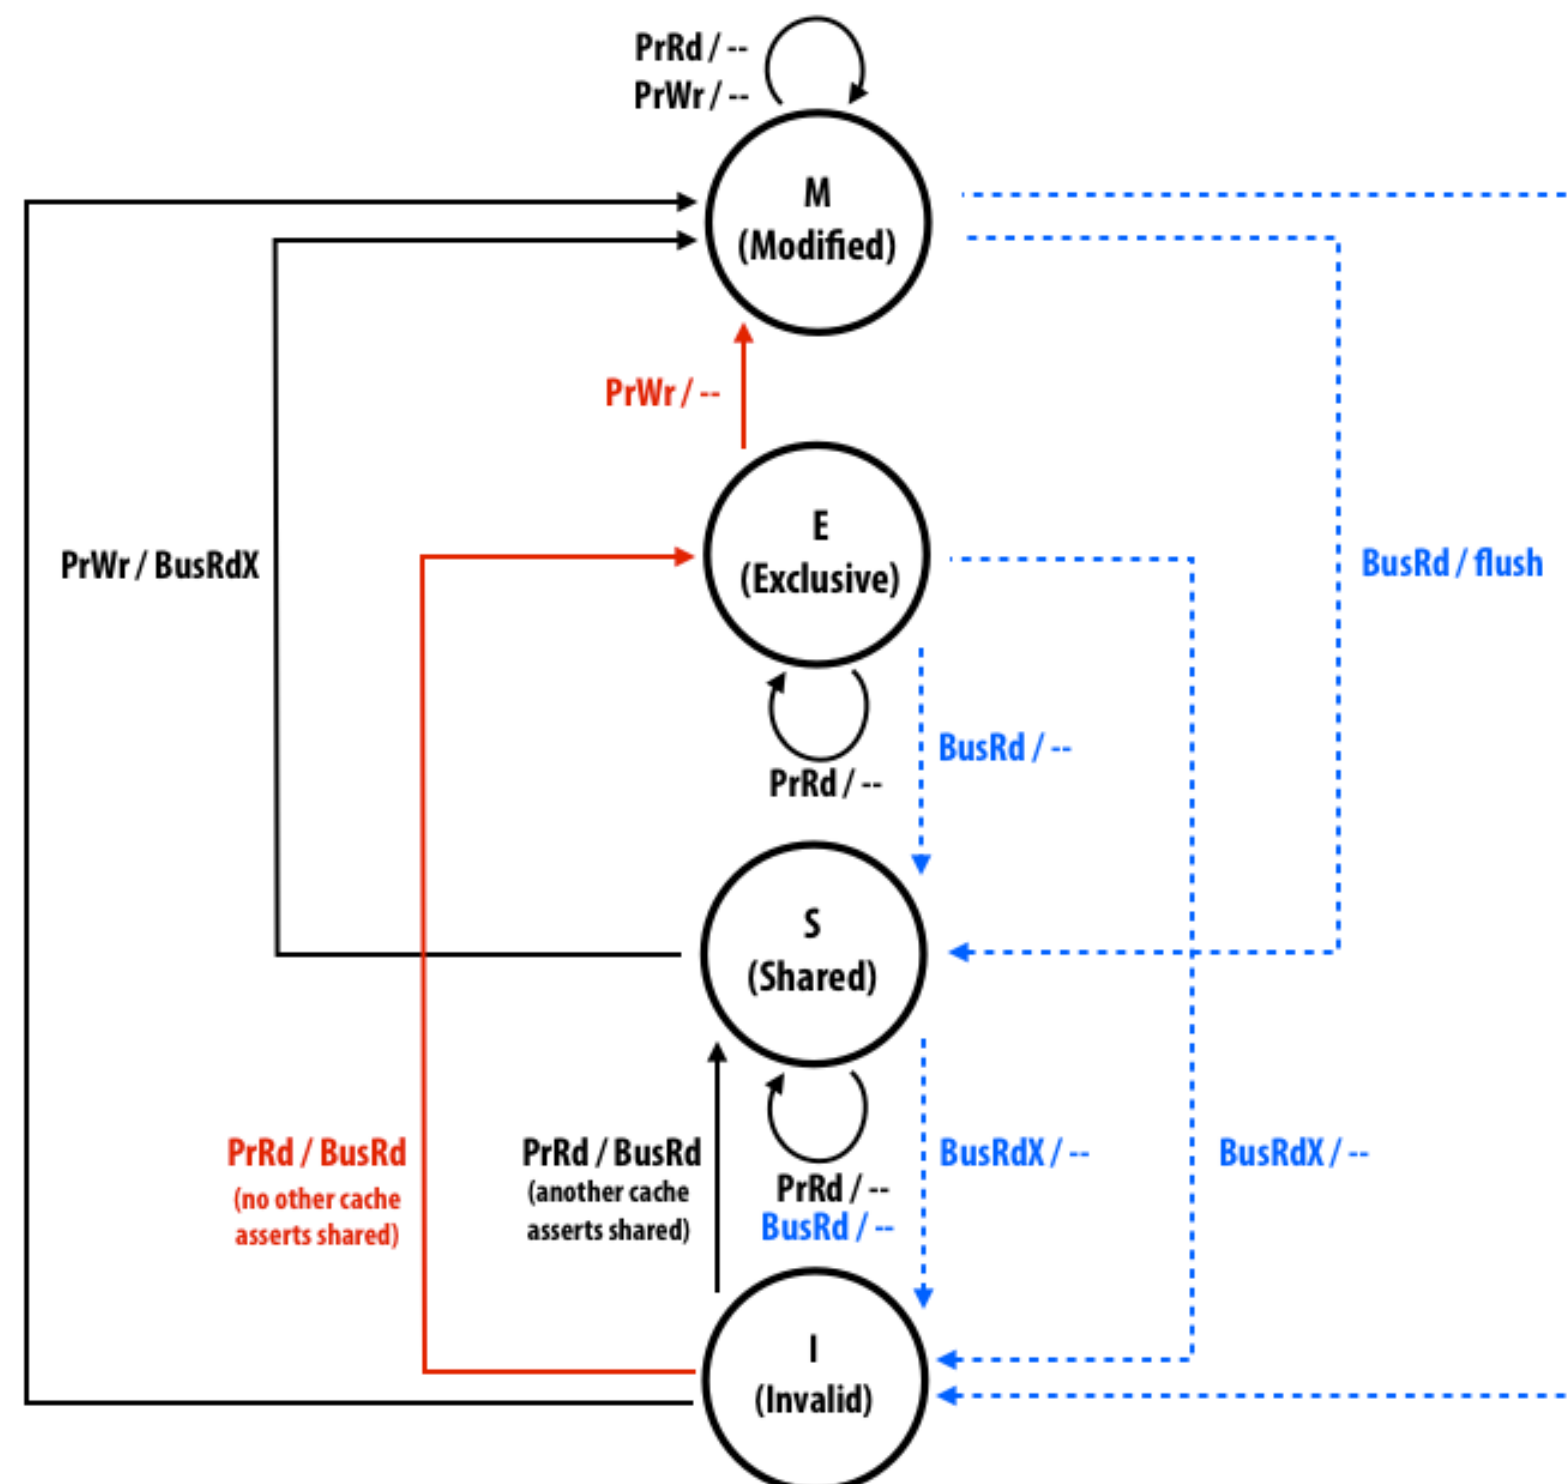

Snoop controller must check the write-back buffer addresses in addition to cache tags.

If there is a write-back buffer match:

- 1. Respond with data from write-back buffer rather than cache**
- 2. Cancel outstanding bus access request (for the write back)**

In practice state transitions are **not atomic**

- Coherence protocol state transition diagrams (like the one below) assumed that transitions between states were atomic
- We've assumed the bus transaction itself is atomic, but all the operations the system performs as a result of a memory operation are not
 - e.g., look up tags, arbitrate for bus, wait for actions by other controllers, ...
- Implementations must be careful to handle race conditions appropriately

An example race condition

Observation: Cache doesn't need data when transitioning $S \rightarrow M$

Common optimization: BusUpg, a new bus transaction that is exactly like BusRdX, except it doesn't need to return data.

Scenario: **P1 and P2 write to valid (and shared) cache line A simultaneously** (both need to issue BusUpg to move line from S state to M state)

1. P1 "wins" bus access (as determined by arbiter), P1 sends BusUpg
2. P2 is waiting for bus access (to send its own BusUpg), can't proceed because P1 has bus
3. P2 receives BusUpg, must invalidate line A (as per MESI protocol)
4. **P2 must also change its pending BusUpg request to a BusRdX!**

Cache must be able to handle requests while waiting to acquire bus AND be able to modify its own outstanding requests

Fetch deadlock

P1 has a modified copy of cache line B

P1 is waiting for the bus so it can issue BusRdX on cache line A

BusRd for B appears on bus while P1 is waiting

To avoid deadlock, P1 must be able to service incoming transactions while waiting to issue requests

Livelock

Two processors writing to cache line B

P1 acquires bus, issues BusRdX

P2 invalidates

Before P1 performs cache line update, P2 acquires bus, issues BusRdX

P1 invalidates

and so on...

To avoid livelock, a write that obtains exclusive ownership must be allowed to complete before exclusive ownership is relinquished.

Self check: when does a write “commit?”

- A write commits when a **read-exclusive transaction appears on bus and is acknowledged by all other caches**
 - At this point, the write is “committed”
 - All future reads will reflect the value of this write (even if data from P has not yet been written to P’s dirty cache line, or to memory)
 - Key idea: order of transactions on the bus defines the global order of writes in the parallel program (write serialization)
- **Commit != complete**: a write completes when the updated value is in the cache line
- Why does a write-back buffer not affect time of commit?

Starvation

- **Multiple processors competing for bus access**
 - **Must be careful to avoid (or minimize likelihood of) starvation**
 - **E.g., what if processor with “lowest id” wins.**
- **Example policies that achieve greater fairness:**
 - **FIFO arbitration**
 - **Round-robin arbitration**
 - **Priority-based heuristics (frequent bus users have priority drop)**

Design issues we have seen

- Design of cache controller and tags
(to support access from processor and bus)
- How and when to present snoop results on bus
- Dealing with write backs
- Dealing with non-atomic state transitions
- Avoiding deadlock, livelock, starvation

These issues arose even though we only implemented a few optimizations on a very basic invalidation-based, write-back system!

(atomic bus, one outstanding memory request per processor, single-level caches)

First-half summary: parallelism and concurrency in coherence implementation are sources of complexity

- **Processor, cache, and bus all are resources operating in parallel**
 - Often contending for shared resources:
 - Processor and bus contend for cache
 - Caches contend for bus access
- “Memory operations” that are **abstracted** by the architecture as **atomic** (e.g., loads, stores) are **implemented** via **multiple transactions** involving all of these hardware components
- Performance optimization often entails **splitting operations into several, smaller transactions**
 - Splitting work into smaller transactions reveals more parallelism (recall pipelining)
 - Cost: more hardware needed to exploit additional parallelism
 - Cost: care needed to ensure abstractions still hold (the machine is correct)

Part 2:

Building the system around non-atomic bus transactions

What you should know

- **What is the major performance issue with atomic bus transactions that motivates moving to a more complex non-atomic system?**
- **You should know the main components of a split-transaction bus, and how transactions are split into requests and responses**
- **The role of queues in a parallel system (today is yet another example)**

Review: transaction on an atomic bus

1. Client is granted bus access (result of arbitration)

Problem: bus is idle while response is pending
(this decreases effective bus bandwidth)

This is bad, because the interconnect is a limited, shared resource in a multi-processor system.
(So it is important to use it as efficiently as possible)

2. Client places command on bus (may also place data on bus)
3. Response to command by another bus client placed on bus
4. Next client obtains bus access (arbitration)

Split-transaction bus

Bus transactions are **split into two transactions**:

1. The **request**
2. The **response**

Other transactions can intervene between a transaction's request and response.

Consider this scenario:

Read miss to A by P1

Bus upgrade of B by P2

Possible timeline of events on a split-transaction bus:

P1 gains access to bus

P1 sends BusRd command

[memory starts fetching data now...]

P2 gains access to bus

P2 sends BusUpg command

Memory gains access to bus

Memory places A on bus

New issues arise due to split transactions

1. How to **match requests with responses**?
2. How to handle **conflicting requests** on bus? Consider:
 - P1 has outstanding request for line A
 - Before response to P1 occurs, P2 makes request for line A
3. **Flow control**: how many requests can be outstanding at a time, and what should be done when buffers fill up?
4. **When are snoop results reported?** During the request? or during the response?

A basic design

- **Up to eight outstanding requests at a time (system wide)**
- **Responses need not occur in the same order as requests**
 - **But request order establishes the total order for the system**
- **Flow control via negative acknowledgements (NACKs)**
 - **When a buffer is full, client can NACK a transaction, causing a retry**

Initiating a request

Can think of a split-transaction bus as two separate buses:
a request bus and a response bus.

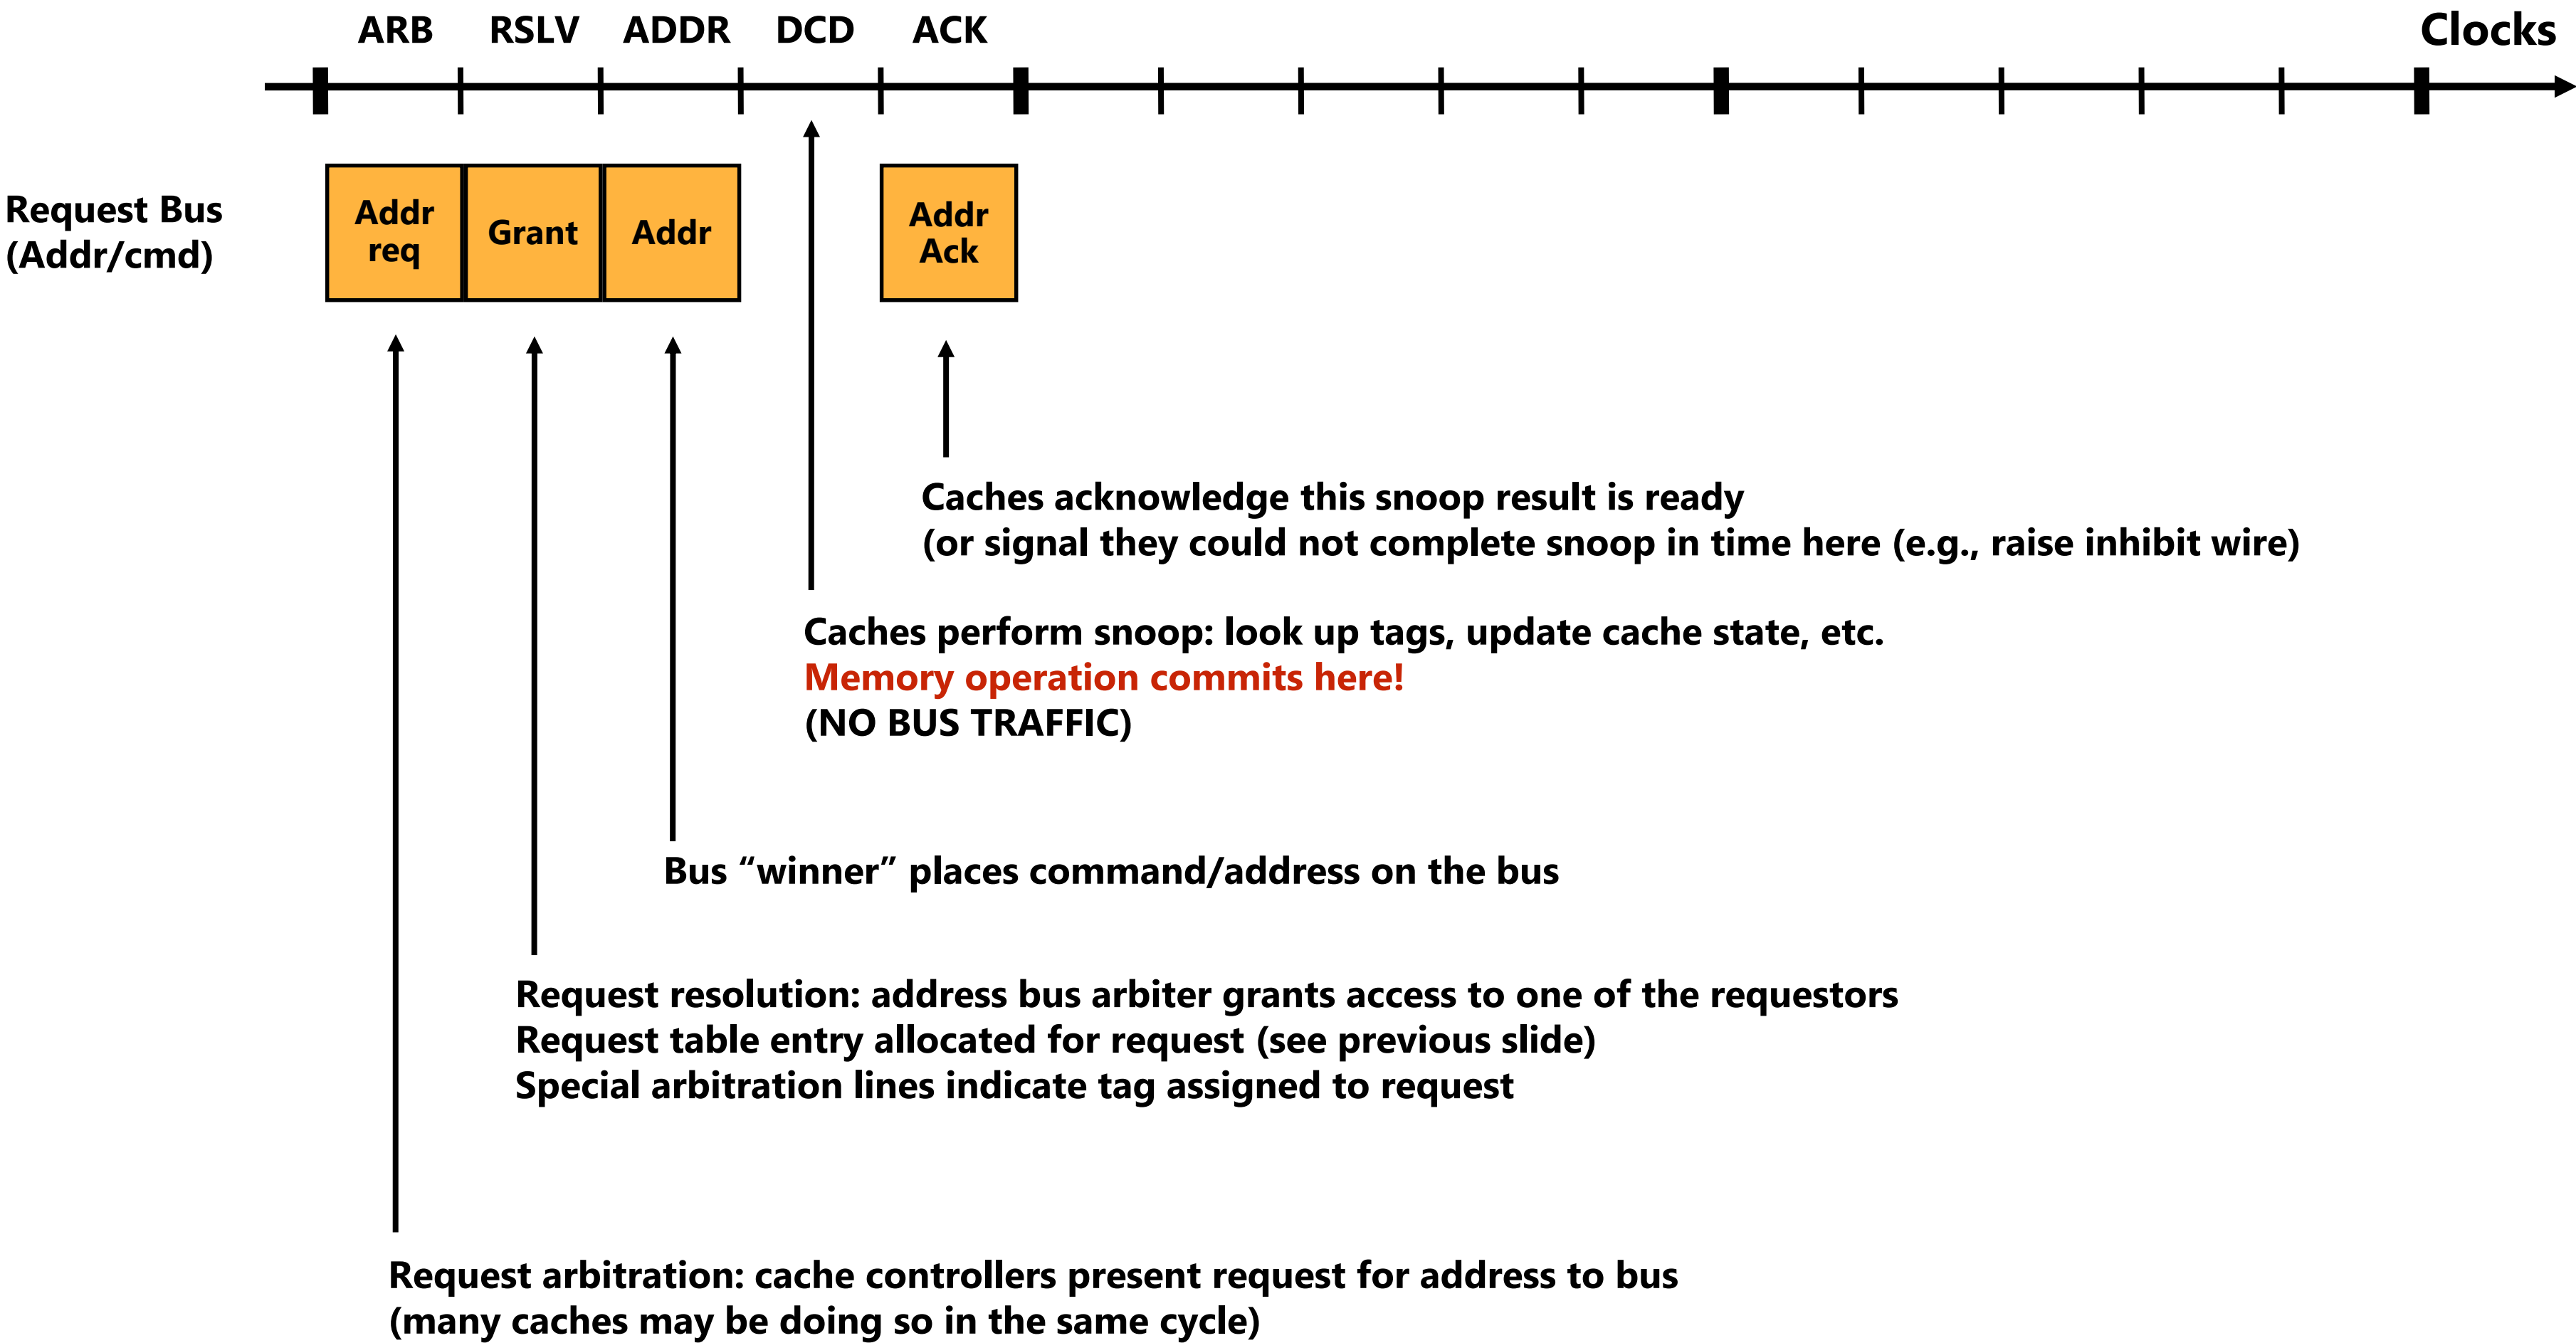

Request Table
(assume a copy of this table is maintained by each bus client: e.g., cache)

Transaction tag is just the index into the request table

Requestor	Addr	State
P0	0xbeef	

- Step 1: Requestor asks for request bus access
- Step 2: Bus arbiter grants access, assigns transaction a tag
- Step 3: Requestor places command + address on the request bus

Read miss: cycle-by-cycle bus behavior (phase 1)

Read miss: cycle-by-cycle bus behavior (phase 2)

Request Bus
(Addr/cmd)

Response Bus
(Data Arbitration)

(Data)

Original requestor signals readiness to receive response
(or lack thereof: requestor may be busy at this time)

Data bus arbiter grants one responder bus access

Data response arbitration: responder presents intent to respond to request with tag T
(many caches --or memory-- may be doing so in the same cycle)

Read miss: cycle-by-cycle bus behavior (phase 3)

Request Bus
(Addr/cmd)

Response Bus
(Data Arbitration)

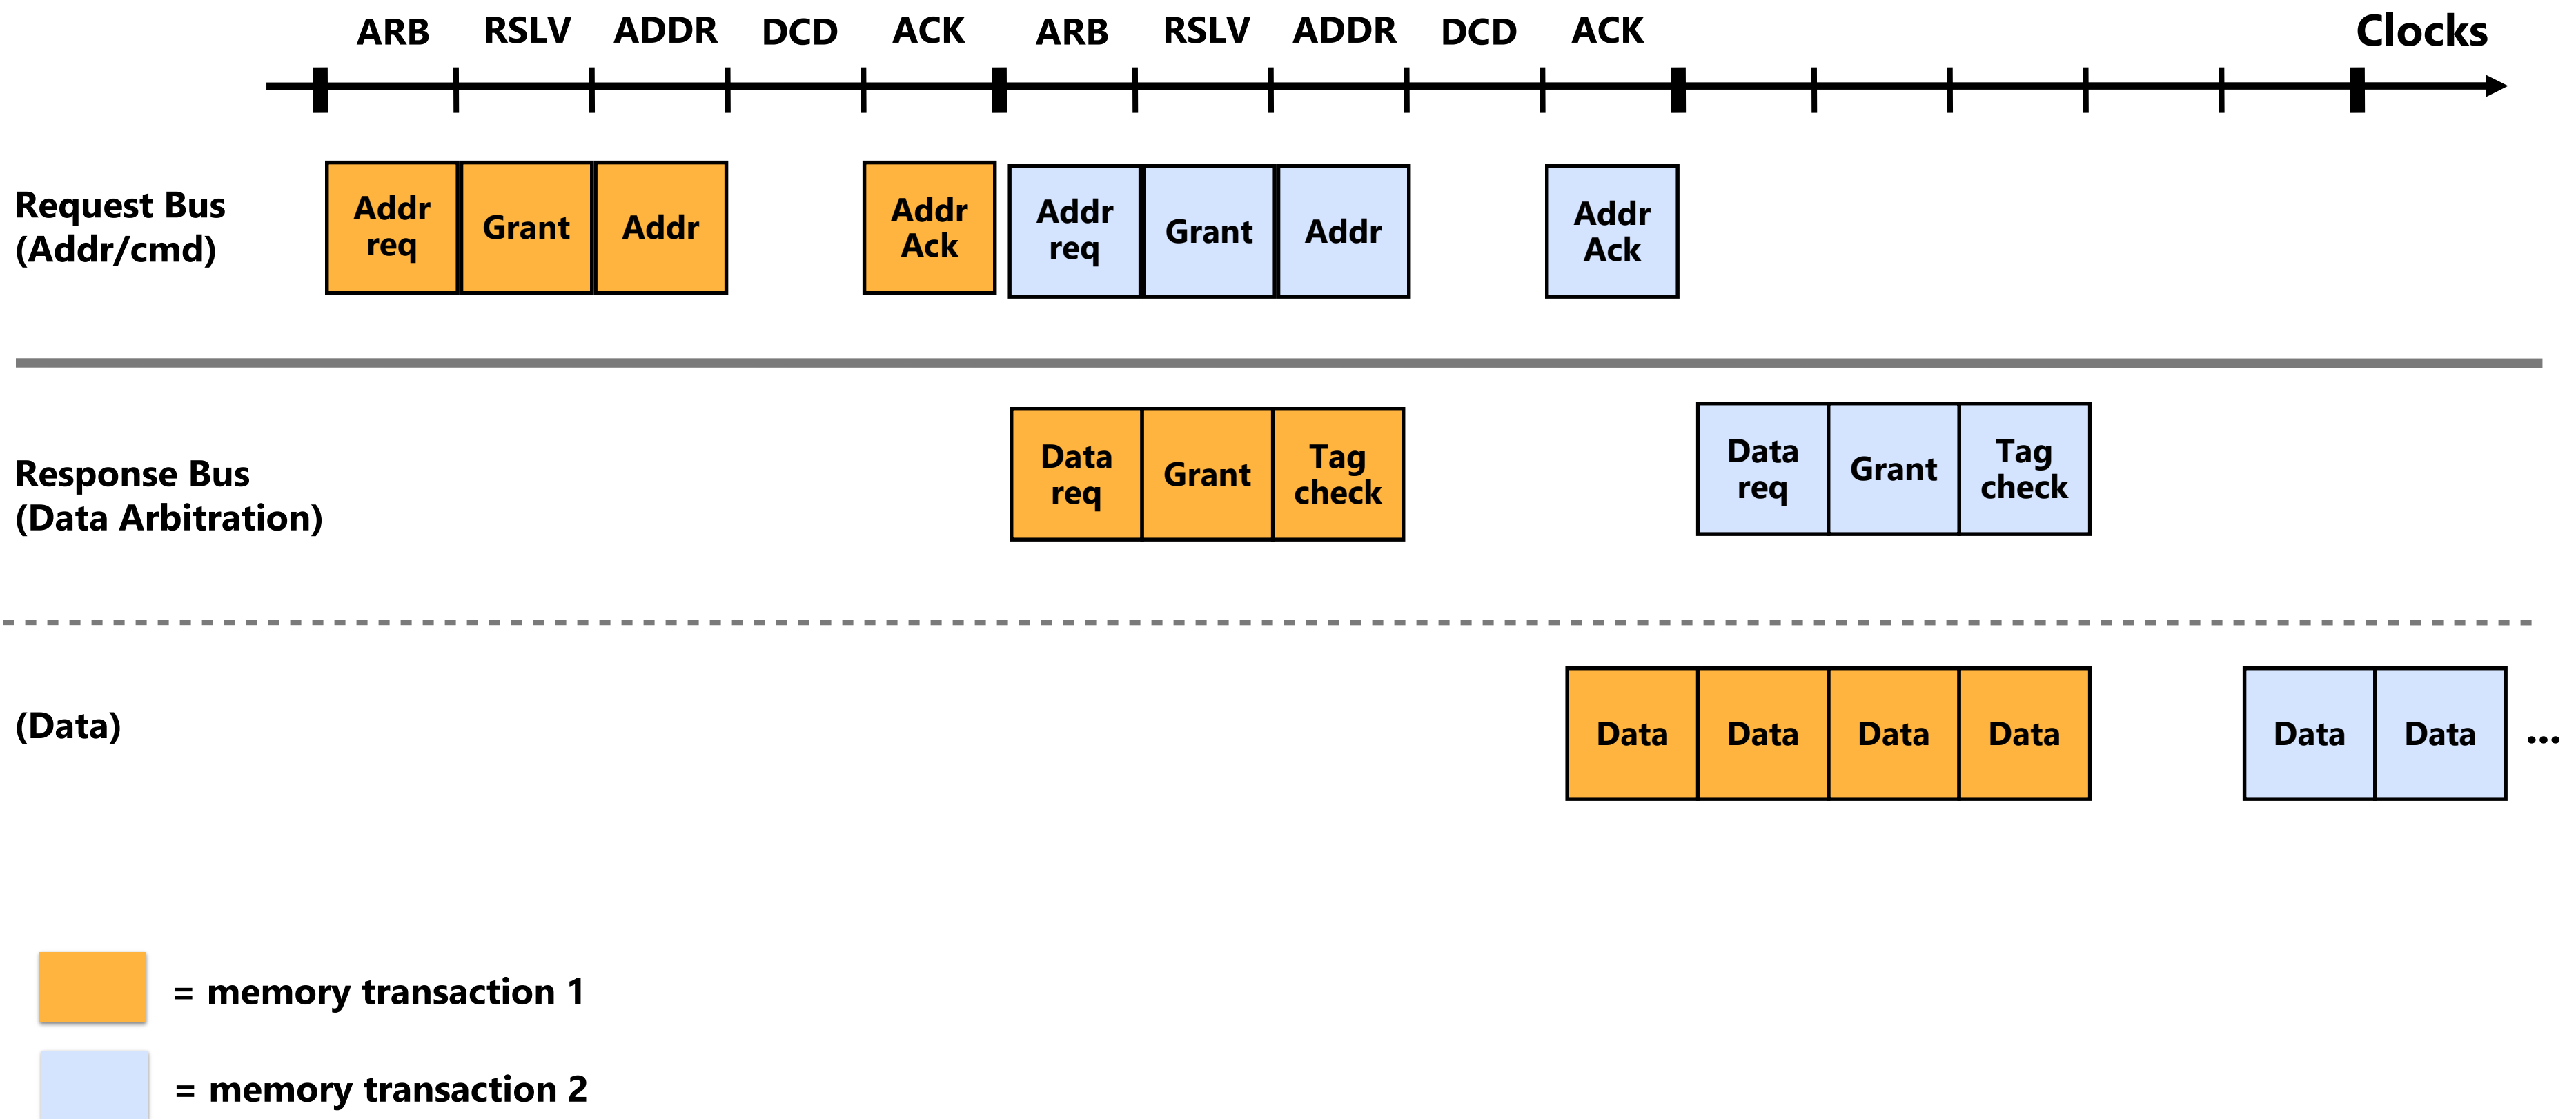

(Data)

Responder places response data on data bus
Caches present snoop result for request with the data
Request table entry is freed
Here: assume 128 byte cache lines → 4 cycles on 256 bit bus

Pipelined transactions

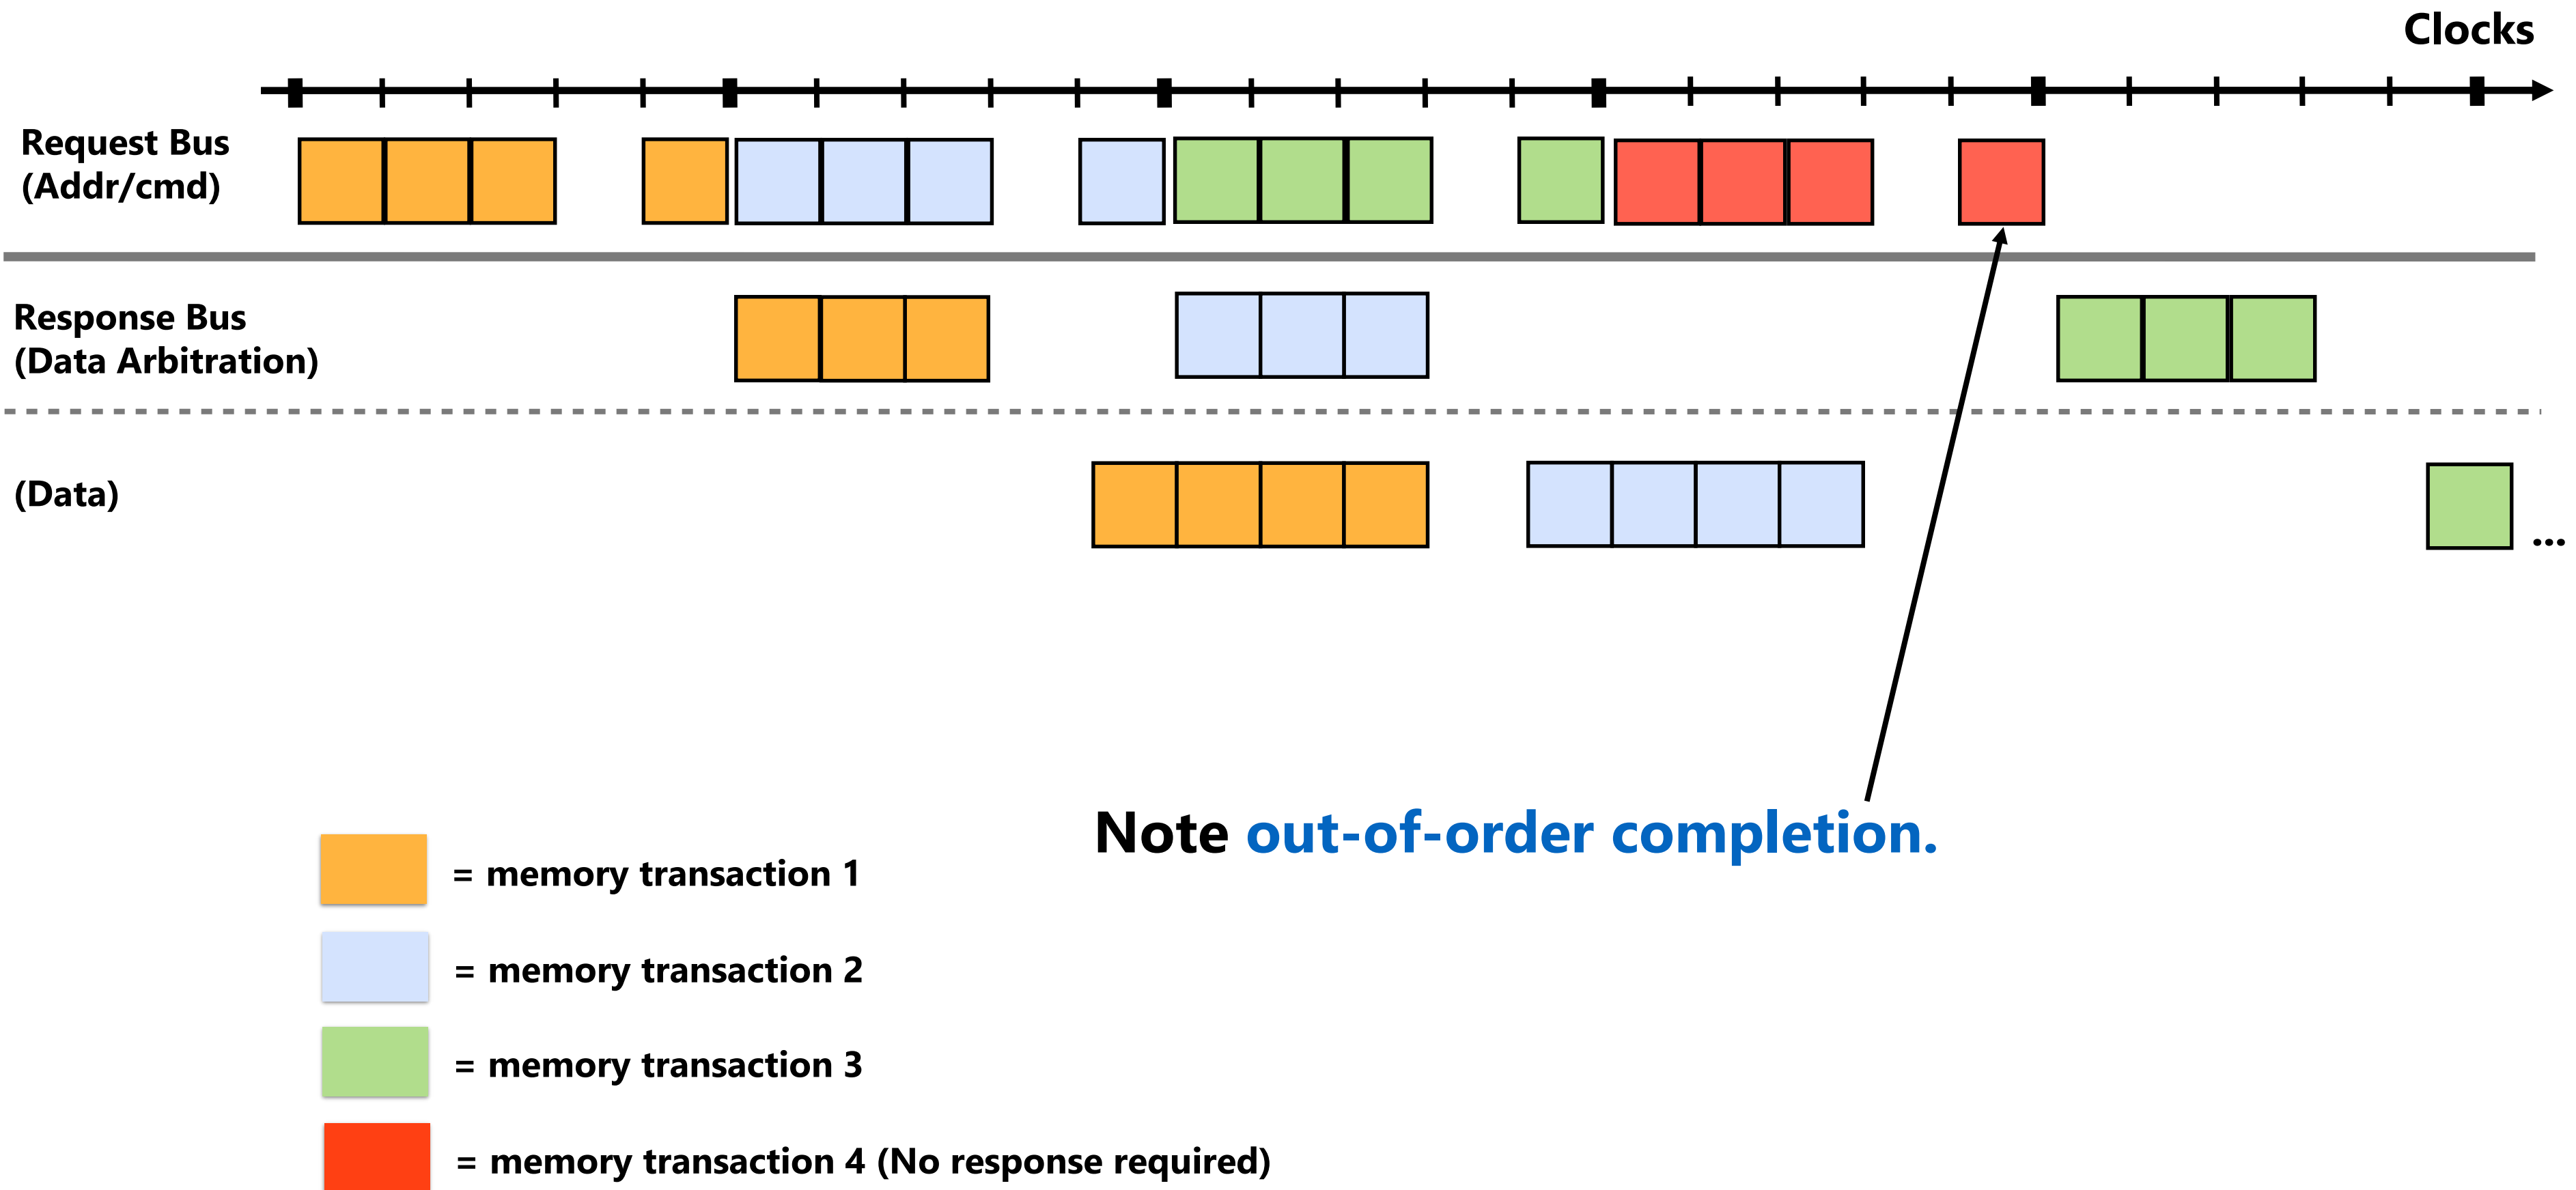

Note: Writebacks and BusUpg transactions do not have a response component

Writebacks acquire access to both request address bus and data bus as part of "request" phase

BusUpg does not need any acknowledgement or data

Pipelined transactions

Key issues to resolve

- **Conflicting requests**

- Avoid conflicting requests by disallowing them
- Each cache has a copy of the request table
- Simple policy: caches do not make requests that conflict with requests in the request table

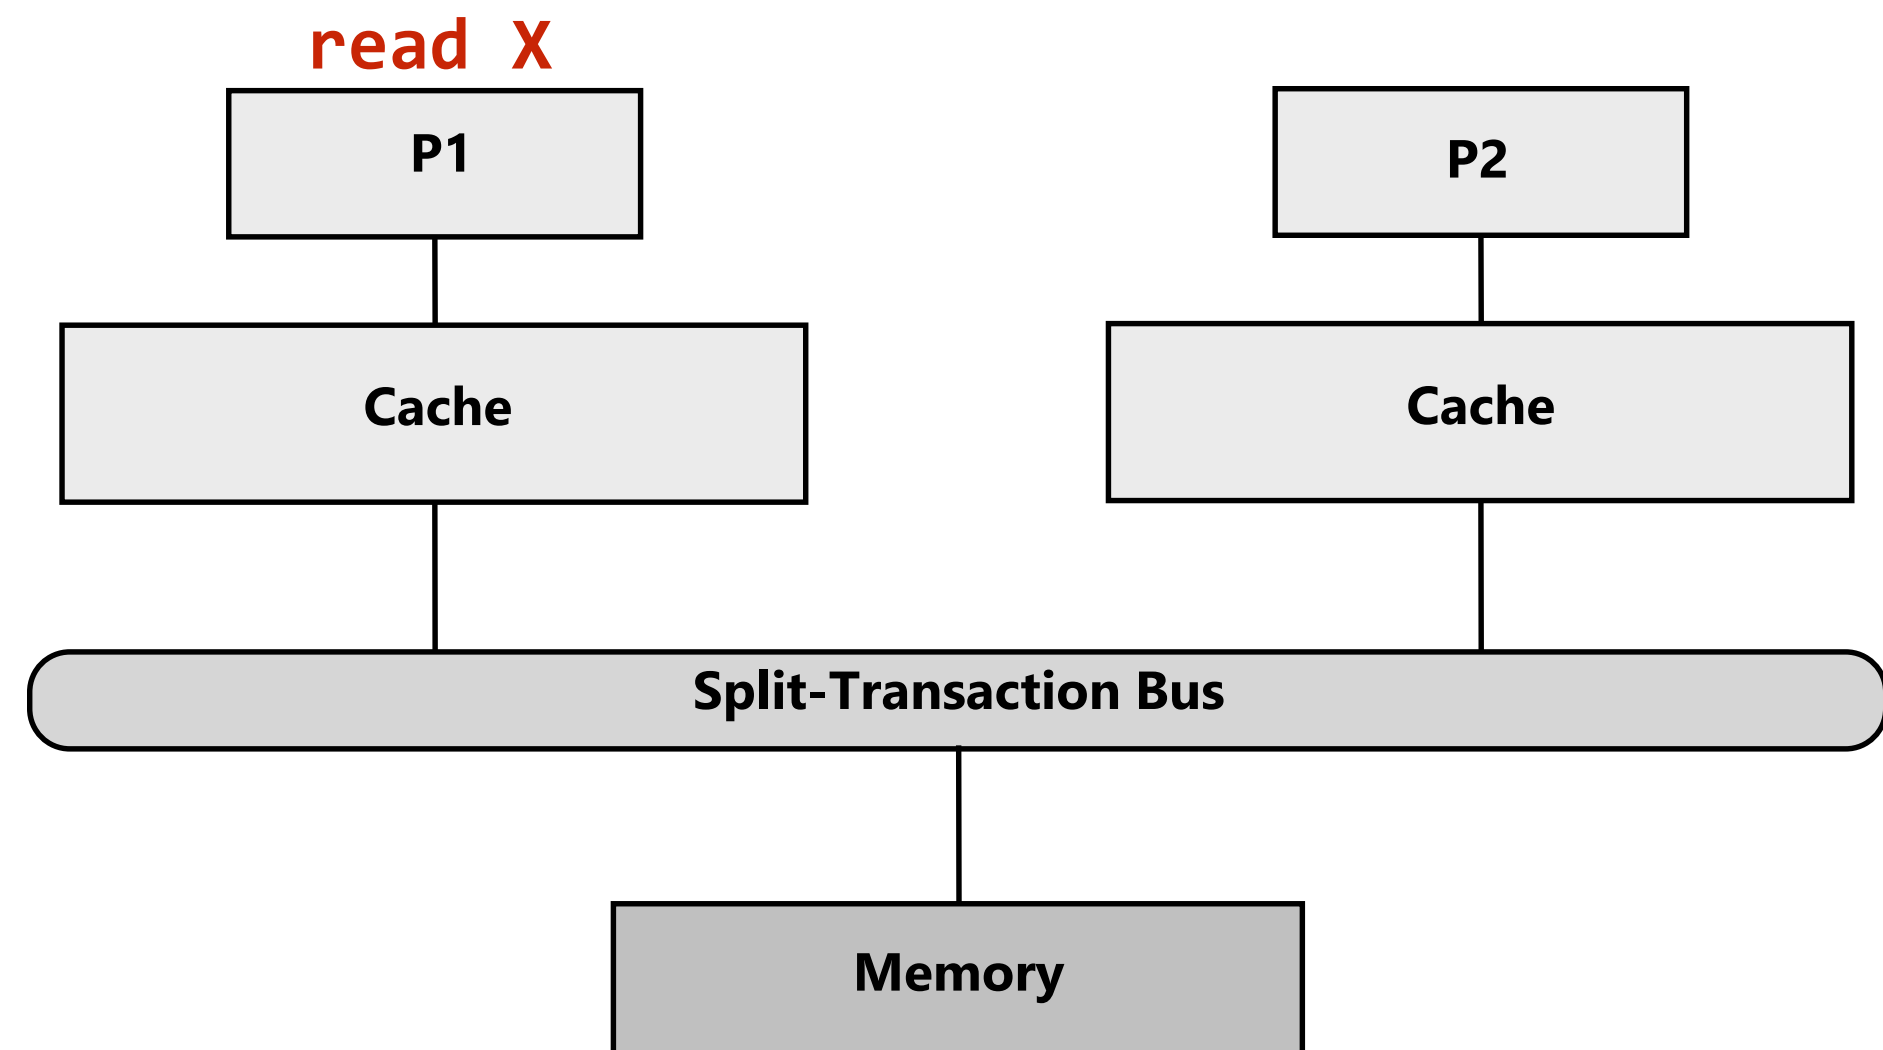

- **Flow control:**

- Caches/memory have buffers for receiving data off the bus
- If the buffer fills, client NACKs relevant requests or responses
(NACK = negative acknowledgement)
- Triggers a later retry

Situation 1: P1 read miss to X, read transaction involving X is outstanding on bus

P1 Request Table

Requestor	Addr	State
P2	X	Op: BusRd, share

If **outstanding request** is a **read**: there is **no conflict**. No need to make a new bus request, just listen for the response to the outstanding one.

Situation 2: P1 read miss to X, write transaction involving X is outstanding on bus

P1 Request Table

Requestor	Addr	State
P2	X	Op: BusRdX

If there is a **conflicting outstanding request** (as determined by checking the request table), **cache must hold request** until conflict clears

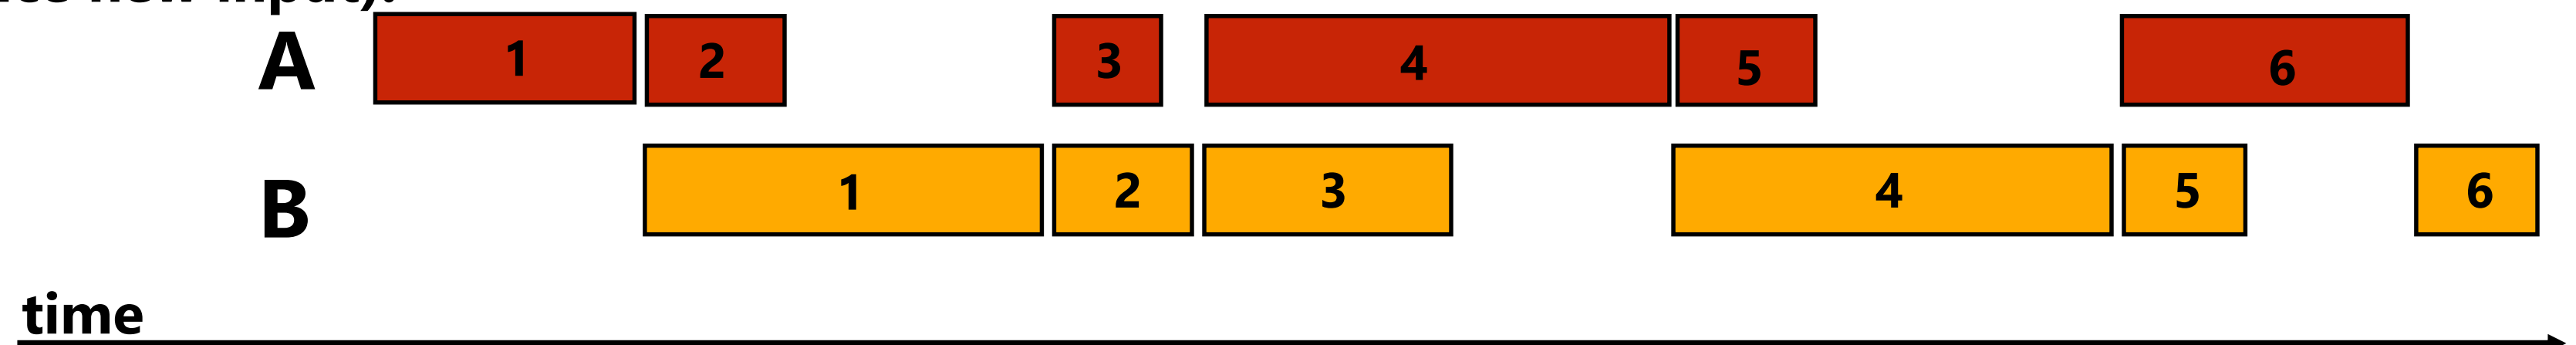

Why do we have queues in a parallel system?

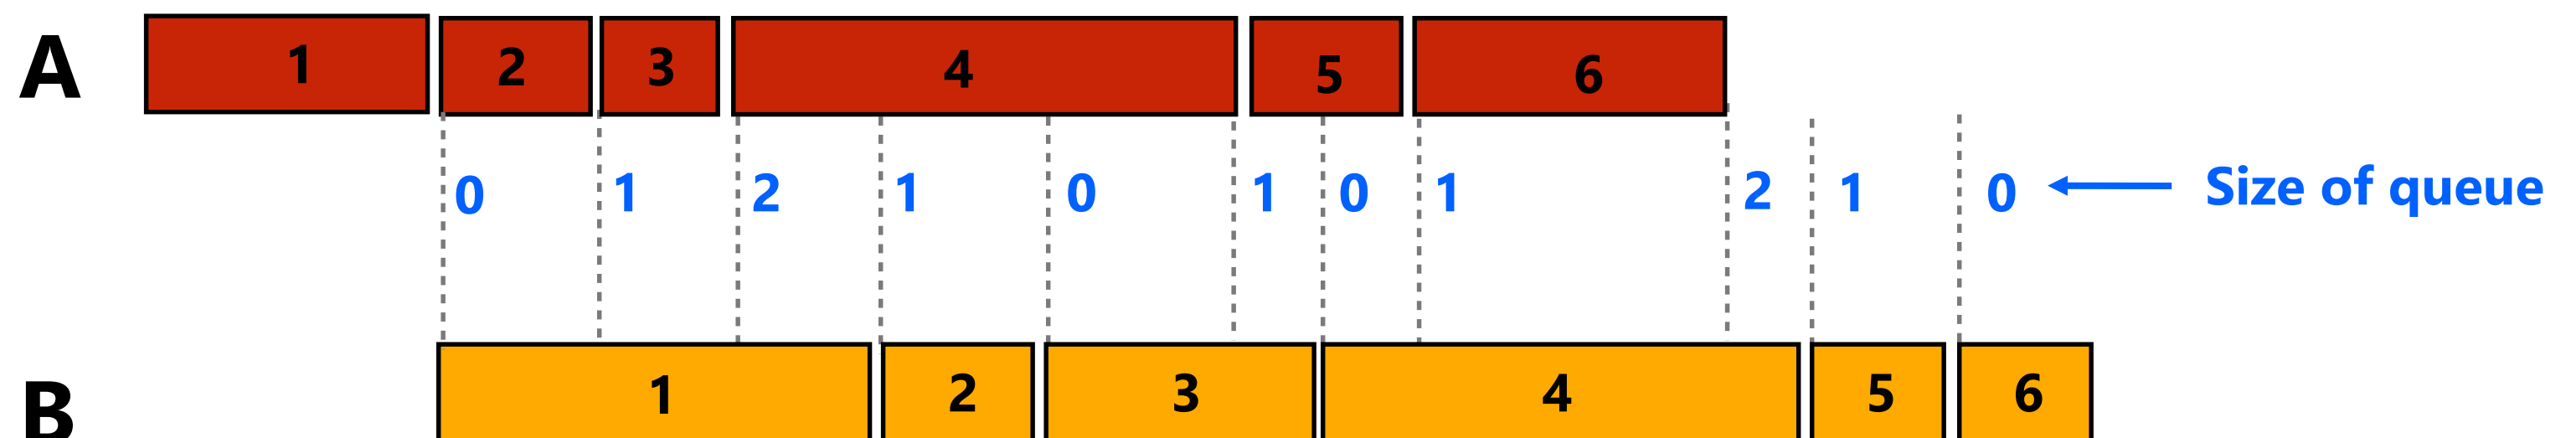

Answer: to accommodate variable (unpredictable) rates of production and consumption.

As long as A and B, on average, produce and consume at the same rate, both workers can run at full rate.

No queue: notice A stalls waiting for B to accept new input (and B sometimes stalls waiting for A to produce new input).

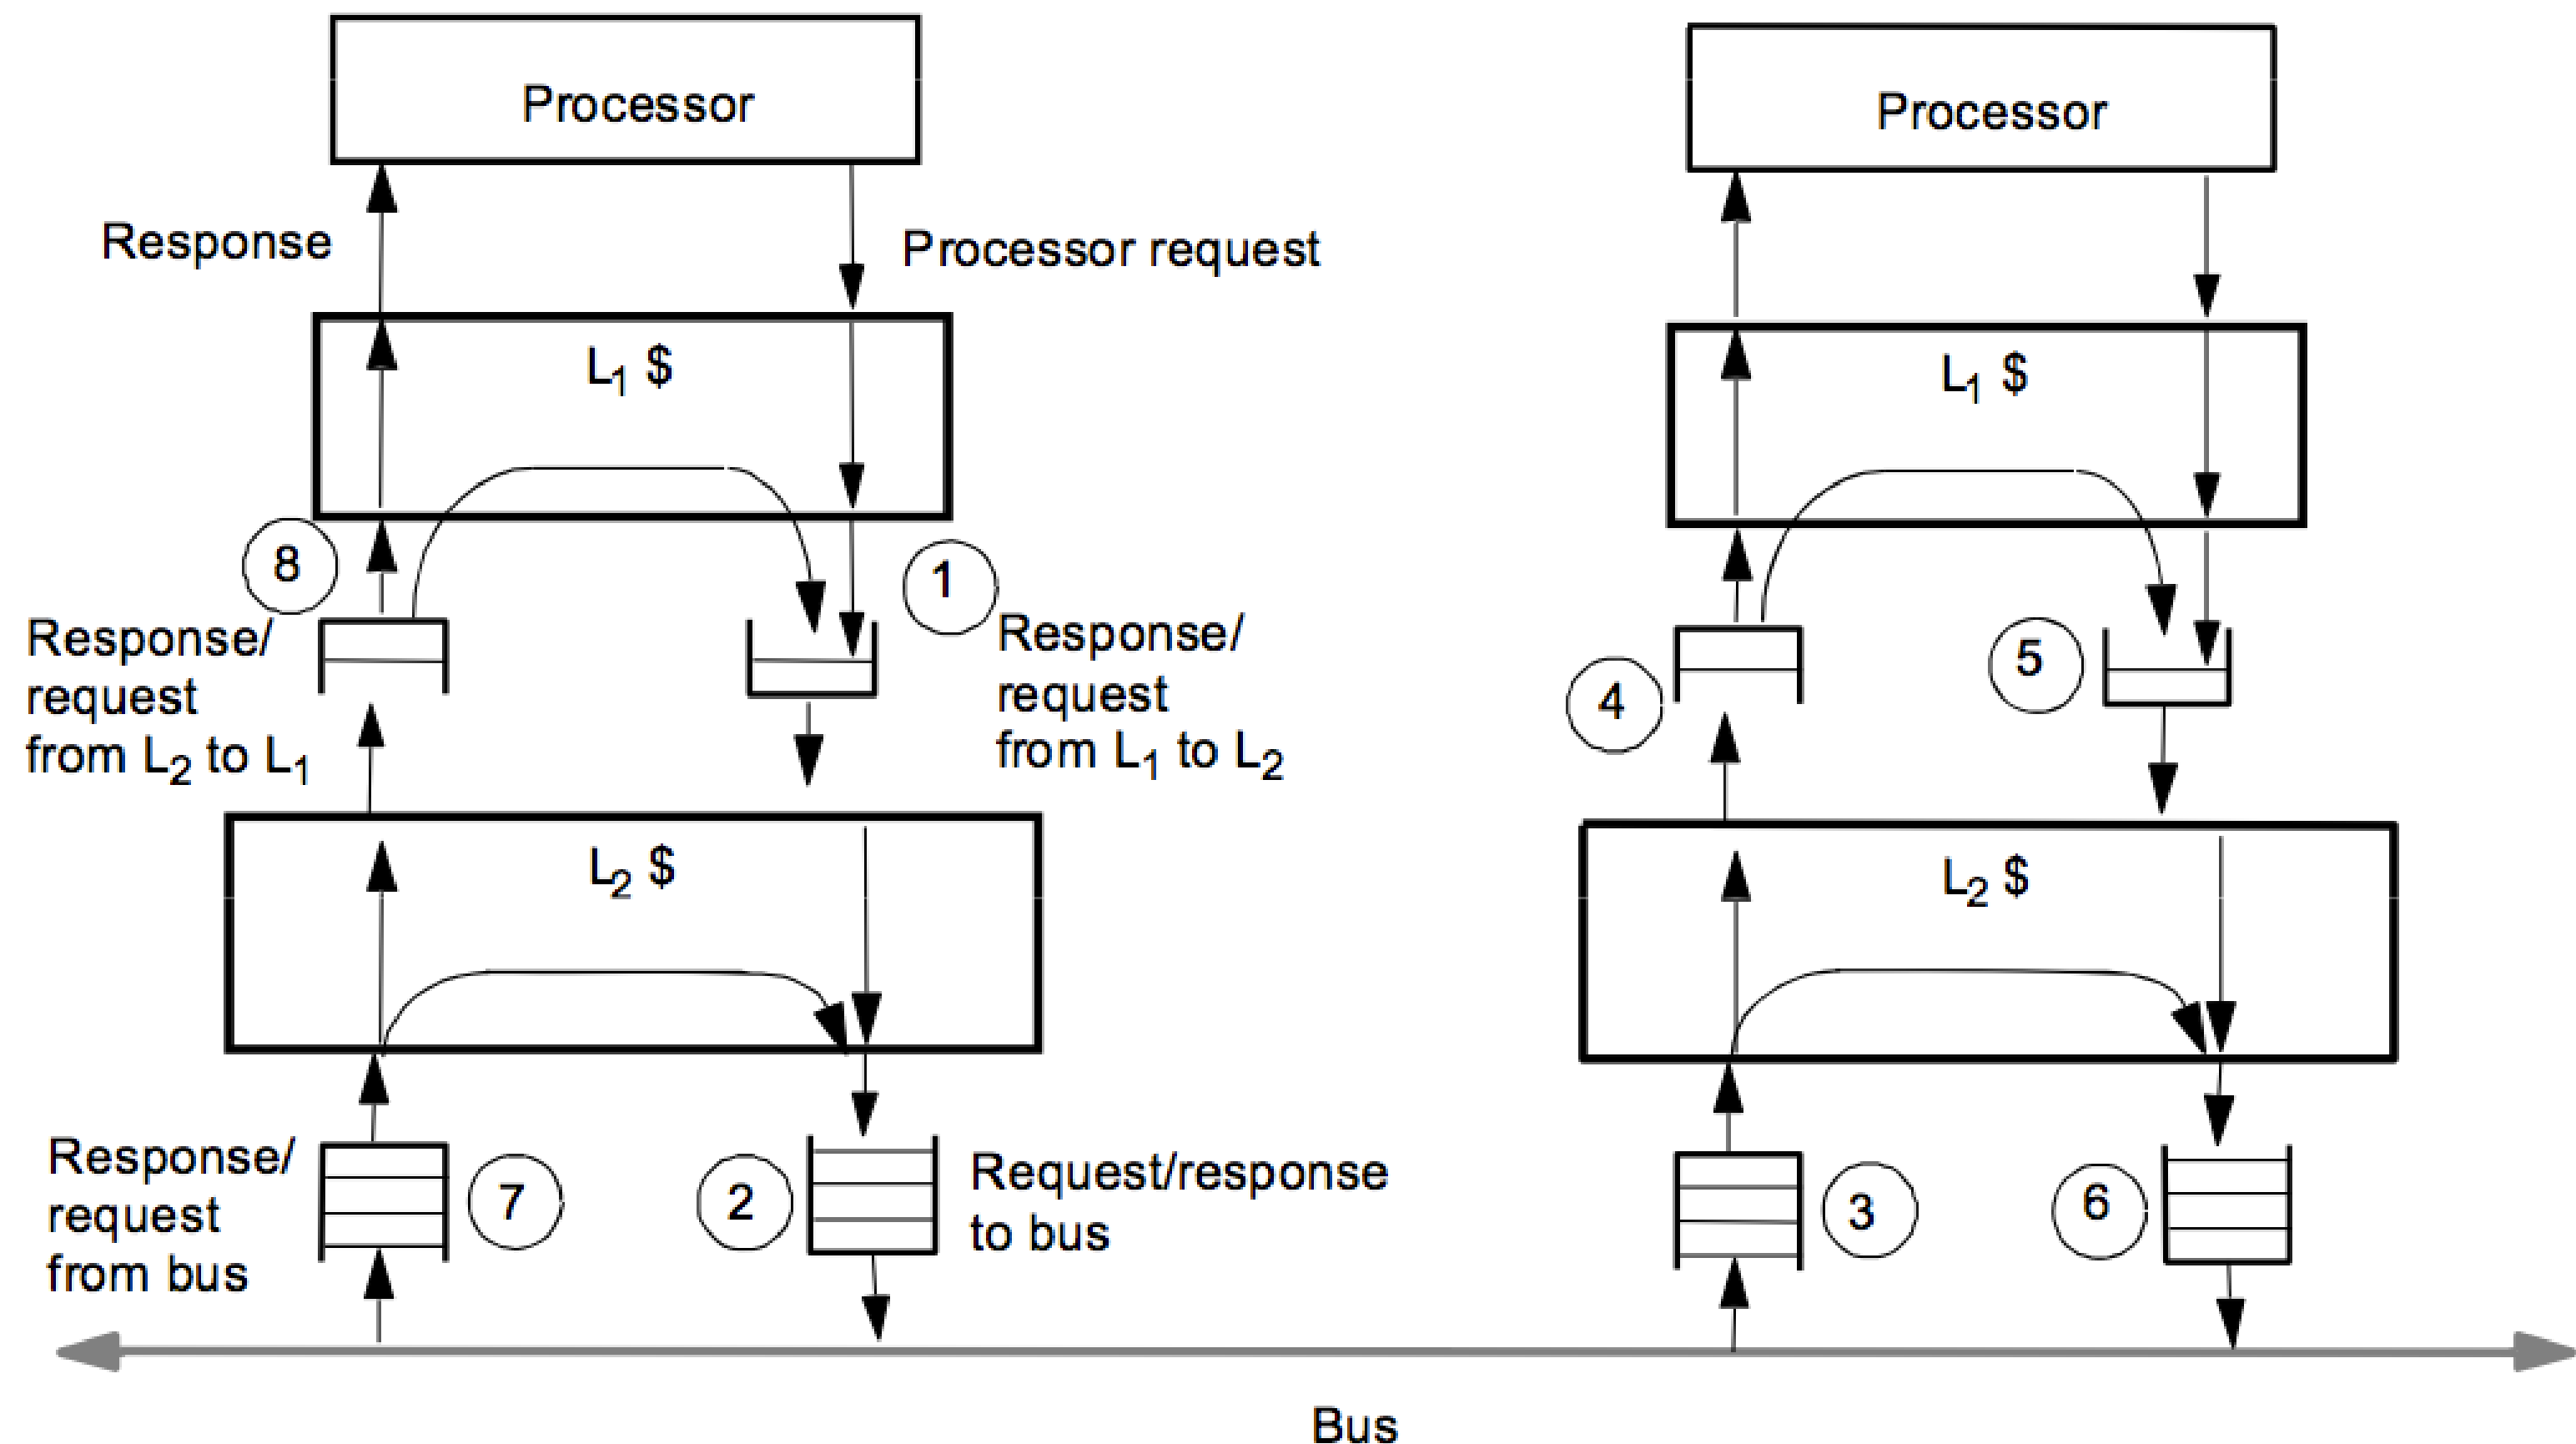

With queue
of size 2: A
and B never
stall

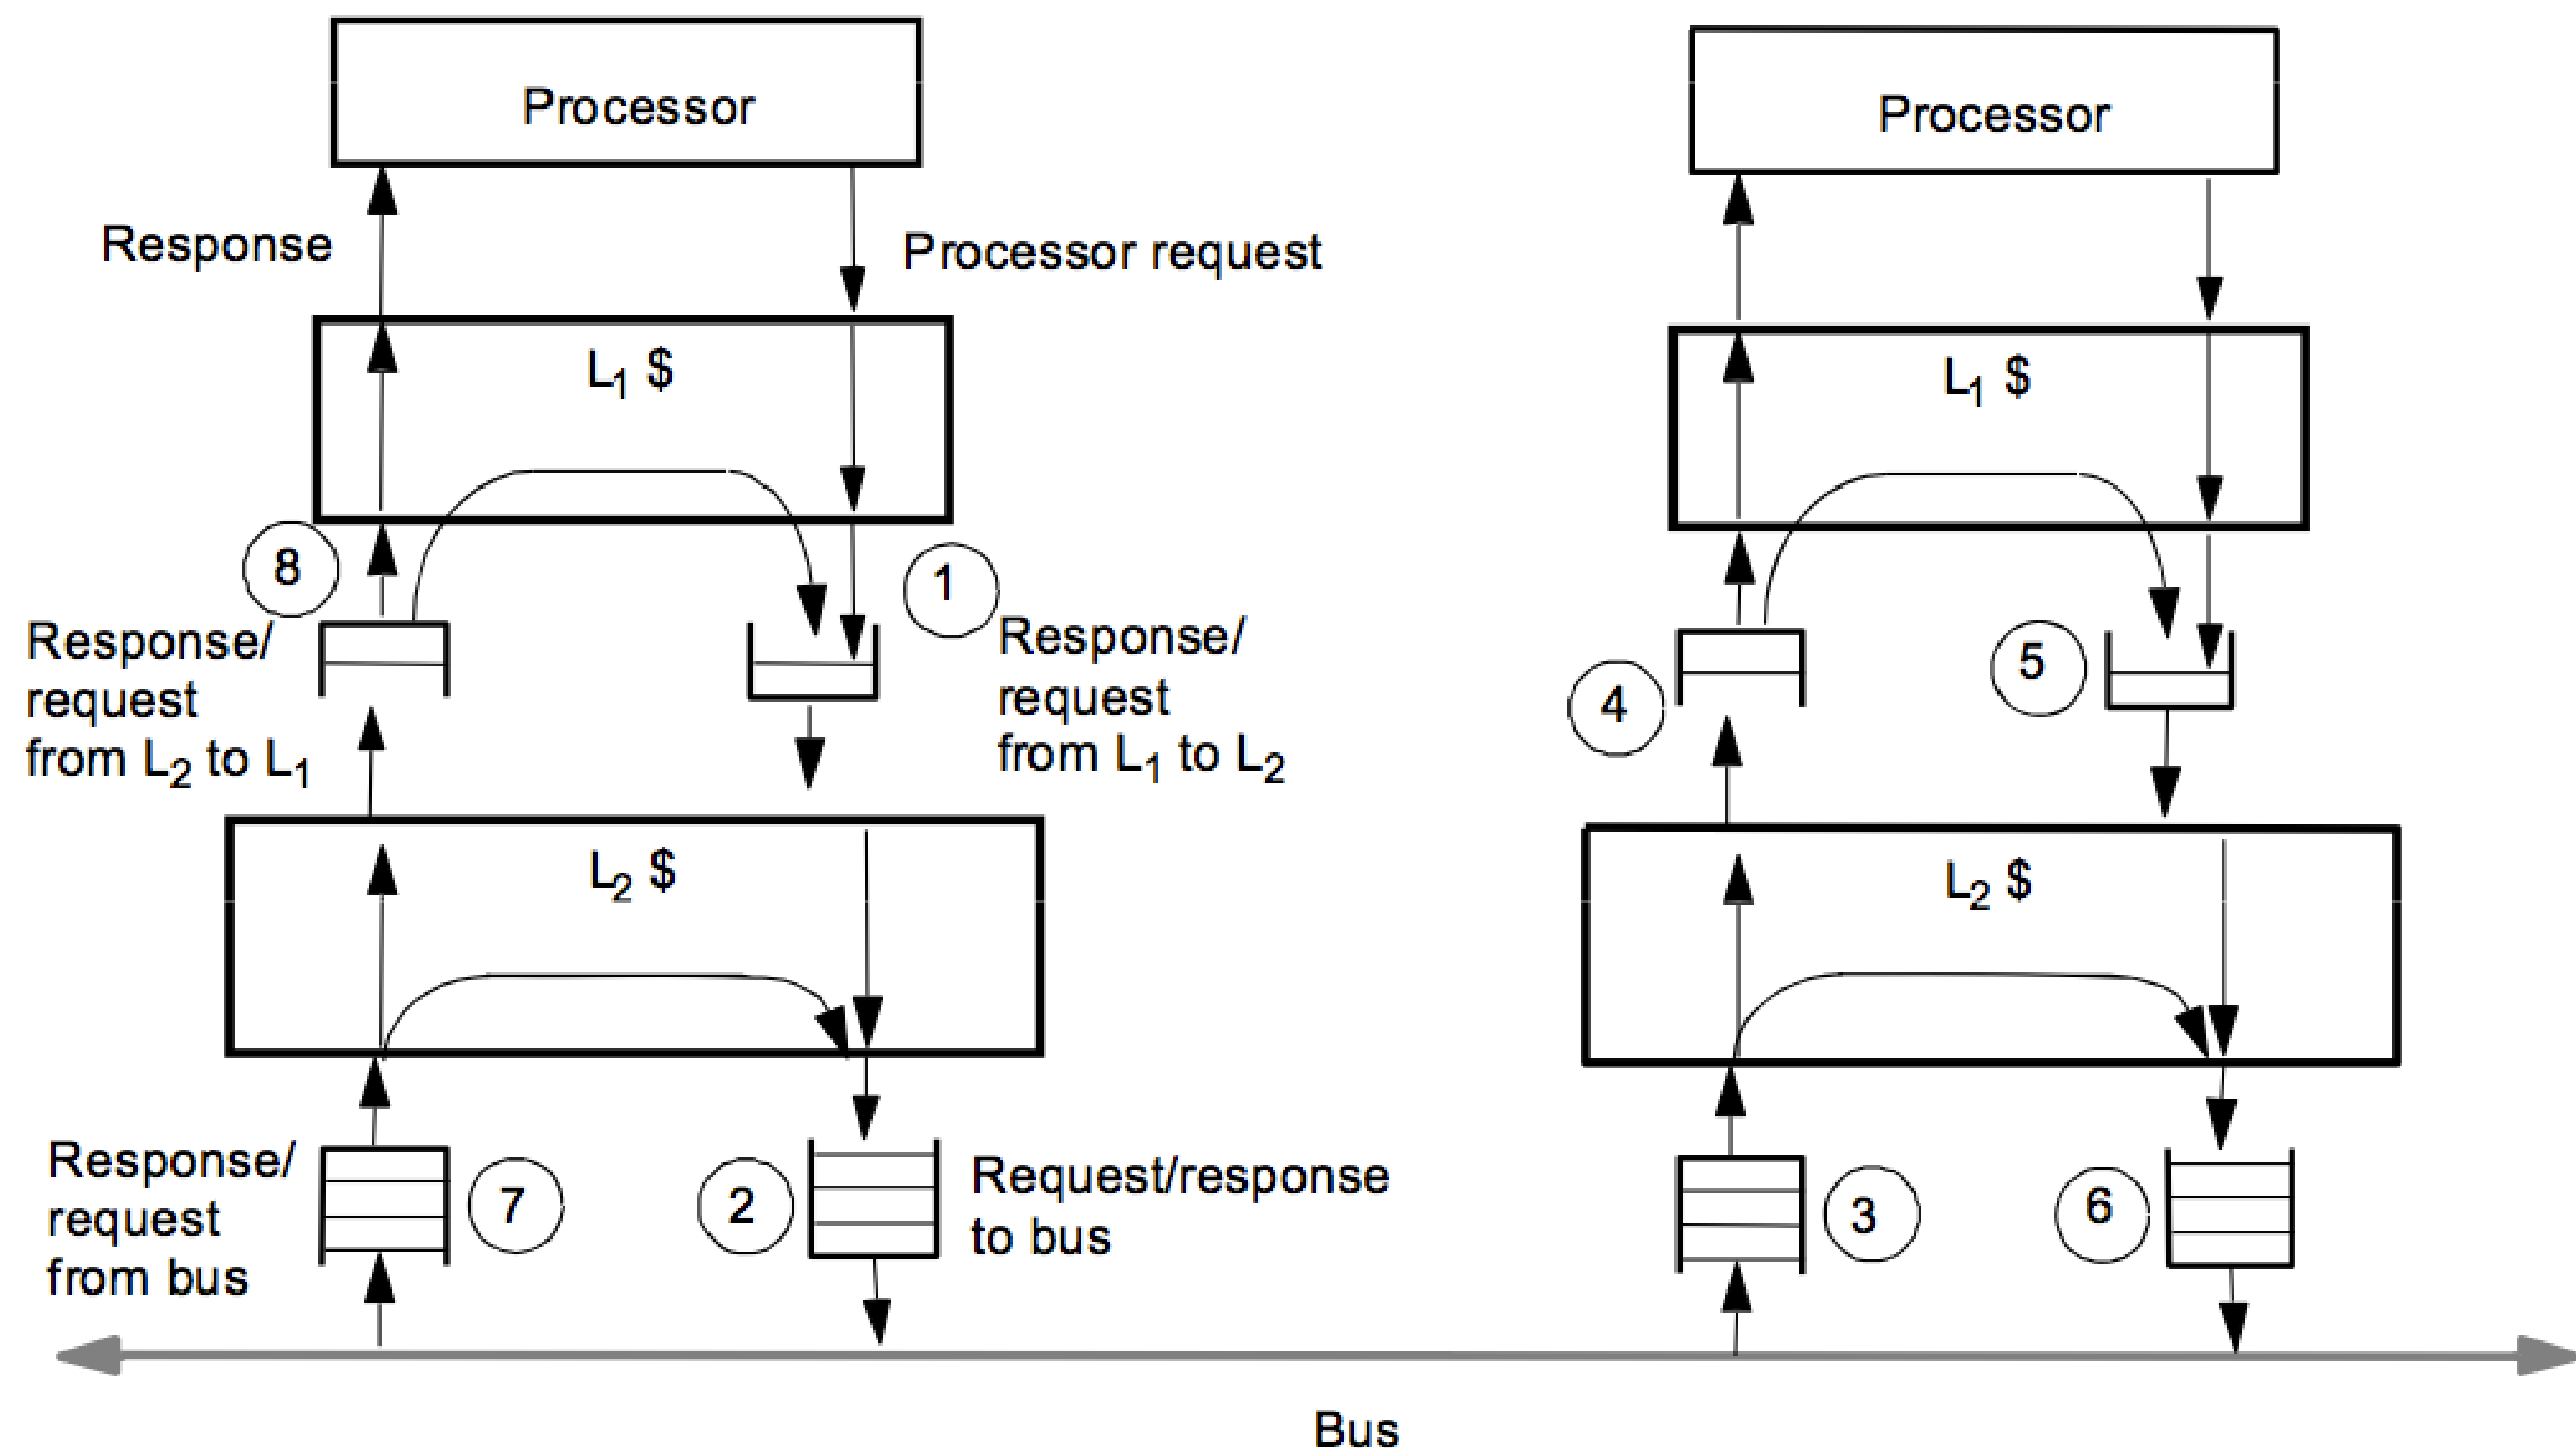

Multi-level cache hierarchies

Numbers indicate steps in a cache miss from processor on left. Serviced by cache on right.

Recall the **fetch-deadlock** problem

Assume one outstanding memory request per processor.

Consider fetch-deadlock problem: **cache must be able to service requests while waiting on response to its own request** (hierarchies increase response delay)

Deadlock due to full queues

Assume buffers are sized so that the maximum queue size is one message. (buffer size = 1)

Outgoing read request (initiated by processor)

Incoming read request (due to another cache) **

Both requests generate responses that require space in the other queue (circular dependency)

** will only occur if L1 is write back

Multi-level cache hierarchies

Assume one outstanding memory request per processor.

Consider fetch deadlock problem: cache must be able to service requests while waiting on response to its own request (hierarchies increase response delay)

Sizing all buffers to accommodate the maximum number of outstanding requests on bus is one solution to avoiding deadlock. But a costly one!

Avoiding buffer deadlock with separate request/response queues

System classifies all transactions as requests or responses

Key insight: responses can be completed without generating further transactions!

Requests INCREASE queue length
But responses REDUCE queue length

While stalled attempting to send a request, cache must be able to service responses.

Responses will make progress (they generate no new work so there's no circular dependence), eventually freeing up resources for requests

Putting it all together

Class exercise: describe everything that might occur during the execution of this statement

```
volatile int x = 10;      // write to memory
```

Class exercise: describe everything that might occur during the execution of this statement *

`volatile int x = 10;`

*** This list is certainly not complete, it's just what I came up with off the top of my head. (This would be a great job interview question!)**

1. Virtual address to physical address conversion (TLB lookup)
2. TLB miss
3. TLB update (might involve OS)
4. OS may need to swap in page to get the appropriate page table (load from disk to physical address)
5. Cache lookup (tag check)
6. Determine line not in cache (need to generate BusRdX)
7. Arbitrate for bus
8. Win bus, place address, command on bus
9. All caches perform snoop (e.g., invalidate their local copies of the relevant line)
10. Another cache or memory decides it must respond (let's assume it's memory)
11. Memory request sent to memory controller
12. Memory controller is itself a scheduler
13. Memory controller checks active row in DRAM row buffer. (May need to activate new DRAM row. Let's assume it does.)
14. DRAM reads values into row buffer
15. Memory arbitrates for data bus
16. Memory wins bus
17. Memory puts data on bus
18. Requesting cache grabs data, updates cache line and tags, moves line into exclusive state
19. Processor is notified data exists
20. Instruction proceeds
